The site selected as the permanent home of our national Science Collections is immediately in rear of the Natural History Museum, and faces the stately edifice, now rapidly progressing towards completion, for the erection of which, as an Imperial memorial of the Queen's Jubilee, funds were provided by voluntary contributions from every portion of the Empire and every class in the Empire's nations. The Imperial Institute, the conception of which we owe to His Royal Highness the Prince of Wales, occupies a central position among buildings devoted to the illustration and cultivation of pure and applied science and of the arts—*i.e.* the Normal School of Science, the Technical College of the City and Guilds of London, the National Schools of Art, the Science Museum, the South Kensington Museum, and the Royal College of Music; to which we may ere long see added a National Gallery of representative British Art. A more fitting location could scarcely be conceived for this pre-eminently national institution, which has for its main objects the comprehensive and continuously progressive illustration—of the practical applications of the vast resources presented by the animal, vegetable, and mineral kingdoms to industries and the arts; of the extent, and the progressive opening up, of those resources in all parts of the Empire; of the practical achievements emanating from the results of scientific research; and of the utilization of the arts for the purposes of daily life. With the attainment of these objects it will be the function of the Imperial Institute to combine the continuous elaboration of systematic measures tending to stimulate progress in trades and handicrafts, and to foster a spirit of emulation among the artisan and industrial classes. Another branch of the Institute's work, upon which it is already engaged, is the systematic collection of data relating to the natural history, commercial geography, and resources of every part of the Empire, for wide dissemination, together with all current information bearing upon the commerce and industries of the Empire and of other countries, which can be comprised under the head of Commercial Intelligence. The achievement of these objects should obviously tend to maintain intimate intercourse, relationship, and co-operation between the great home and colonial centres of commerce, industries, and education, and to enhance importantly our power of competing successfully in the great struggle, in which nations are continuously engaged, for supremacy in commercial and industrial enterprise and prosperity.

To the elaboration of the practical details of a system of operation calculated to secure the objects I have indicated, eminent public-spirited men are now devoting their best energies, with the sanguine expectation of realizing the hope cherished by the Royal Founder of the Imperial Institute, that this memorial of the completion, by our beloved Sovereign, of fifty years of a wise and prosperous reign, is destined to be one of the most important bulwarks of this country, its colonies and depend-

encies, by becoming a great centre of operations, ceaselessly active in fostering the unity, and developing the resources, and thus maintaining and increasing the power and prosperity, of our Empire.

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY PROF. T. E. THORPE, B.SC., PH.D., F.R.S., TREAS.C.S., PRESIDENT OF THE SECTION.

LEEDS has one most notable association with chemistry of which she is justly proud. In the month of September 1767, Dr. Joseph Priestley took up his abode in this town. The son of a Yorkshire cloth-dresser, he was born, in 1733, at Fieldhead, a village about six miles hence. His relatives, who were strict Calvinists, on discovering his fondness for books, sent him to the academy at Daventry to be trained for the ministry. In spite of his poverty and of certain natural disadvantages of speech and manner, he gradually acquired, more especially by his controversial and theological writings, a considerable influence in Dissenting circles. A pressing invitation and the offer of one hundred guineas a year induced him to accept an invitation to take charge of the congregation of Mill Hill Chapel here. He was already known to science by his "History of Electricity," and the effort was made to attach him still more closely to its cause by the offer of an appointment as naturalist to Cook's second expedition to the South Seas. But, thanks to the intervention of some worthy ecclesiastics on the Board of Longitude who had the direction of the business, and who, as Prof. Huxley once put it, "possibly feared that a Socinian might undermine that piety which in the days of Commodore Trunnion so strikingly characterized sailors," he was allowed to remain in Leeds, where, as he tells us in his "Memoirs," he continued six years, "very happy with a liberal, friendly, and harmonious congregation," to whom his services (of which he was not sparing) were very acceptable. "In Leeds," he says, "I had no unreasonable prejudices to contend with, and I had full scope for every kind of exertion."[1]

We have every reason to feel grateful to the "worthy ecclesiastics," since their action indirectly occasioned Priestley to turn his attention to chemistry. The accident of living near a brewery led him to study the properties of "fixed air," or carbonic acid, which is abundantly formed in the process of fermentation, and which at that time was the only gas whose separate and independent existence had been definitely established. From this happy accident sprang that extraordinary succession of discoveries which earned for their author the title of the Father of Pneumatic Chemistry, and which were destined to completely change the aspect of chemical theory and to give it a new and unexpected development.

I have been led to make this allusion to Priestley, not so much on account of his connection with this place as for the reason that, as it seems to me, there has been a disposition to obscure his true relation to the marvellous development of chemical science which made the close of the last century memorable in the history of learning. Our distinguished fellow-worker, M. Berthelot, the Perpetual Secretary of the French Academy, has recently published, under the title of "La Révolution Chimique," a remarkable book, written with great skill, and with all the charm of style and perspicacity which invariably characterizes his work, in which he claims for Lavoisier a participation in discoveries which we count among the chief scientific glories of this country. From the eminence of M. Berthelot's position in the world of science, his book is certain to receive in his own country the attention which it merits, and as it is issued as one of the volumes of the Bibliothèque Scientifique Internationale, it will probably obtain through the medium of translations a still wider circulation. I trust that I shall not be accused of being unduly actuated by what Mr. Herbert Spencer terms "the bias of patriotism" in deeming the present a fitting occasion on which to bring these claims to your notice with a view of determining how far they can be substantiated.

All who are in the least degree familiar with the history of chemical science during the last hundred years will recognize, as I proceed, that the claims which M. Berthelot asserts on behalf of his illustrious predecessor are not put forward for the first time. Explicitly made, in fact, by Lavoisier himself, they were uniformly and consistently disallowed by his contemporaries. M. Berthelot now seeks to support them by additional evidence, and to strengthen them with new arguments, and asks us thereby to clear the memory of Lavoisier from certain grave charges which lie heavily on it. You have doubtless anticipated that these claims have reference to Lavoisier's position in relation to the discovery of oxygen gas and the determination of the non-elementary nature of water.

The substance we now call oxygen—a name we owe to Lavoisier—was discovered by Priestley on August 1, 1774; he obtained it, as every schoolboy knows, by the action of heat upon the red oxide of mercury. We all remember the characteristically ingenuous account which Priestley gives of the origin of his discovery. M. Berthelot sees in it merely the evidence of the essentially empirical character of his work. "Priestley," he says, "the enemy of all theory and of every hypothesis, draws no general conclusion from his beautiful discoveries, which he is pleased, moreover, not without affectation, to attribute to chance. He describes them in the current phraseology of the period with an admixture of peculiar and incoherent ideas, and he remained obstinately attached to the theory of phlogiston up to his death, which occurred in 1804" (p. 40). Such a statement is calculated to give an erroneous idea of Priestley's merit as a philosopher. That the implication it contains is wholly opposed to the real spirit of his work might be readily shown by numerous quotations from his writings. Perhaps this will suffice:—"It is always our endeavour, after making experiments, to generalize the conclusions we draw from them, and by this means to form a *theory* or system of principles to which all the *facts* may be reduced, and by means of which we may be able to foretell the result of future experiments." This quotation is taken from the concluding chapter of his "Experiments and Observations on Different Kinds of Air," in which he actually seeks to draw "general conclusions" concerning the constituent principles of the various gases which he himself made known to us, and to show the bearing of these conclusions on the doctrine of phlogiston. That he was content to rest in the faith of Stahl's great generalization, even to the end, is true, and the fact is the more remarkable when we recall the absolute sincerity of the man, his extraordinary receptivity, and, as he says of himself, his proneness "to embrace what is generally called the heterodox side of almost every question." If it is argued that this merely shows Priestley's inability to appreciate theory, it must be at least admitted that there is no proof that he was inimical to it. His position is clearly evident from the concluding words of the section of his work from which I have already quoted:—"This doctrine of the composition and decomposition of water has been made the basis of an entirely new system of chemistry, and a new set of terms has been invented and appropriated to it. It must be acknowledged that substances possessed of very different properties may, as I have said, be composed of the same elements in different proportions and different modes of combination. It cannot, therefore, be said to be absolutely *impossible* but that water may be composed of these two elements or any other. But then the supposition should not be admitted without *proof*; and if a former theory will sufficiently account for all the *facts* there is no occasion to have recourse to a new one, attended with no peculiar advantage (*loc. cit.*, p. 543). . . . I should not feel much reluctance to adopt the *new doctrine*, provided any new and stronger evidence be produced for it. But though I have given all the attention that I can to the experiments of M. Lavoisier, &c., I think that they admit of the easiest explanation on the *old system*" (*loc. cit.*, p. 563).

The fact that Priestley was the first to consciously isolate oxygen is not contested by M. Berthelot, although he is careful to point out, what is not denied, that the exact date of the discovery depends on Priestley's own statement, and that his first publication of it was made in a work published in London in 1775. It was known before Priestley's famous experiment that the red oxide of mercury, originally formed by heating the metal in contact with air, would again yield mercury by the simple action of heat and without the intervention of any reducing agent. Bayen, six months before the date of Priestley's discovery, had observed that a gas was thus disengaged, but he gave no description of its nature, contenting himself merely by pointing out the analogy which his experiments appeared to possess to those of Lavoisier on the existence of an elastic fluid in certain substances. Afterwards, when the facts were established, Bayen drew attention to

[1] Leeds still enjoys one of the fruits of Priestley's insatiable power of work in her admirable Proprietary Library. He seems to have suggested its formation, and was its first honorary secretary.

his earlier experiments, and claimed, not only the discovery of oxygen, but all that Lavoisier deduced from it. "But," says M. Berthelot, in reference to this circumstance, "his contemporaries paid little heed to his pretensions, nor will posterity pay more" ("La Révolution Chimique," p. 60).

M. Berthelot, however, does not dismiss Lavoisier's claims to a participation in the discovery in the same summary fashion. On the contrary, whilst not explicitly claiming for him the actual isolation, in the first instance, of oxygen, the whole tenor of his argument is to extenuate, and even to justify, his demand to be regarded as an independent discoverer of the gas. He begins by asserting that Lavoisier had already a presentiment of its existence in 1774, and he quotes, in support of this assumption, an abstract from Lavoisier's memoir, published in December 1774, in the *Journal de Physique* of the Abbé Rozier: "This air, deprived of its fixable portion (by metals during calcination), is in some fashion decomposed, and this experiment would seem to afford a method of analyzing the fluid which constitutes our atmosphere, and of examining the principles of which it is composed. . . . I believe I am in a position to affirm that the air, as pure as it is possible to suppose it, free from moisture and from every foreign substance, far from being a simple body, or element, as is commonly thought, should be placed, on the contrary, . . . in the group of the mixtures, and perhaps even in that of the compounds."

M. Berthelot further asserts that Lavoisier was at this time the first to recognize the true character of air, and he expresses his belief that it is probable that he would himself have succeeded in isolating its constituents if the path of inquiry had been left to him alone. It is no disparagement to Lavoisier's prescience to say that there is nothing in these lines, nor in the memoir of the repetition of Boyle's experiments on the calcination of tin to which they refer, to show that Lavoisier had made any advance beyond the position of Hooke and Mayow. It has been more than once pointed out that the chemists of the seventeenth century understood the true nature of combustion in air much better than their brethren of the last quarter of the eighteenth century. Hooke, in the "Micrographia," and Mayow, in his "Opera Omnia Medicophysica," indicated that combustion consists in the union of something with the body which is being burnt; and Mayow, both by experiment and inference, demonstrated in the clearest way the analogy between respiration and combustion, and showed that in both processes one constituent only of the air is concerned. He distinctly stated that, not only is there increase of weight attending the calcination of metals, but that this increase is due to the absorption of the same *spiritus* from the air that is necessary to respiration and combustion. Mayow's experiments are so precise, and his facts so incontestable, that, as Chevreul has said, it is surprising that the truth was not fully recognized until a century after his researches (*vide* Watts's "A Dictionary of Chemistry," by Morley and Muir, Art. "Combustion," p. 242).

It is now necessary to examine Lavoisier's claims rather more closely and in the light of M. Berthelot's book. A *résumé* of his work "On the Calcination of Tin" was given by Lavoisier to the Academy in November 1774, but the complete memoir was not deposited until May 1777. A careful comparison of an abstract of what was stated to the Academy in November 1774, contributed by Lavoisier himself, in December 1774, to the *Journal de Physique* of the Abbé Rozier, makes it evident that very substantial additions were made to the communication before it was finally printed in the *Mémoires de l'Académie des Sciences*. The possibility of this is allowed by M. Berthelot. He says:—"A summary communication, often given *vivâ voce* to a learned Society, such as the Academy of Sciences of Paris or the Royal Society of London, would immediately call forth verifications, ideas, and new experiments, which would develop the range and even the results of such communication. The original author, when printing his memoir, would in return —and for this he is hardly blamable—embody these additional results and later interpretations. It thus becomes most difficult to assign impartially to each his share in a rapid succession of discoveries" (*loc. cit.*, p. 58).

But although, as we shall see, Lavoisier was certainly aware of Priestley's great discovery, no allusion is made to the gas, nor to Priestley's previous work on the other constituent of air, which is printed in the Philosophical Transactions for 1772, and for which he was awarded the Copley Medal by the Royal Society. It is simply impossible to believe that Lavoisier could have been uninfluenced by this work. Indeed, we venture to assert that the full and clear recognition of the non-elementary nature of the air which he eventually made was based upon it. It is noteworthy that in the early part of his memoir he states his opinion that the addition, not only of powdered charcoal, but of any phlogistic substance to a metallic calx is attended with the formation of fixed air. It is certain that at this period he had not only not consciously obtained any gas resembling Priestley's dephlogisticated air from any calx with which he had experimented, but that none of his experiments had afforded him any idea that the gas absorbed during calcination was identical with it.

At Easter 1775, Lavoisier presented a memoir to the Academy "On the Nature of the Principle which Combines with Metals during Calcination." This was "*relu le* 8 *août*, 1778." To the memoir there is a note stating that the first experiments detailed in it were performed more than a year before; those on the red precipitate were made by means of *a burning-glass* in the month of November 1774, and were repeated in the spring of 1775 at Montigny in conjunction with M. Trudaine. In this paper Lavoisier first distinctly announces that the principle which unites with metals during their calcination, which increases their weight, and which transforms them into calces, is nothing else "than the purest and most salubrious part of the air; so that if that air which has been fixed in a metallic combination again becomes free, it reappears in a condition in which it is eminently respirable, and better adapted than the air of the atmosphere to support inflammation and the combustion of substances" ("Œuvres de Lavoisier," official edition, vol. ii. p. 123). He then describes the method of preparing oxygen by heating the red oxide of mercury, and compares its properties with those of fixed air. There is, however, no mention of Priestley, nor any reference to his experiments. It can hardly be doubted that in this memoir Lavoisier intended his readers to believe that he was "the true and first discoverer" of the gas which he afterwards named oxygen. This is borne out by certain passages in his subsequent memoir "On the Existence of Air in Nitrous Acid; *lu le* 20 *avril*, 1776, *remis en décembre* 1777." He had occasion incidentally to prepare the red oxide of mercury by calcining the nitrate, and says that he obtained from it a large quantity of an air "much purer than common air, in which candles burnt with a much larger, broader, and more brilliant flame, and which in no one of its properties differed from that which *I* had obtained from the calx of mercury, known as *mercurius precipitatus per se*, and which Mr. Priestley had procured from a great number of substances by treating them with nitric acid."

In another part of this memoir he says that "perhaps, strictly speaking, there is nothing in it of which Mr. Priestley would not be able to claim the original idea; but as the same facts have conducted us to diametrically opposite results, I trust that, if I am reproached for having borrowed my proofs from the works of this celebrated philosopher, my right at least to the conclusions will not be contested." M. Berthelot remarks on the irony of this passage: we may infer from it that the friends of the English chemist had not been altogether idle. In his memoir "On the Respiration of Animals," read to the Academy in 1777, he again appears to admit the claim of Priestley to at least a share in the discovery: "It is known from Mr. Priestley's and my experiments that *mercurius precipitatus per se* is nothing but a combination," &c. In several subsequent communications Priestley's name is mentioned in very much the same connection, until we come to the classical memoir "On the Nature of the Acids," when it is said: "I shall henceforth designate the dephlogisticated air, or the eminently respirable air, . . . by the name of the *acidifying principle*, or, if it is preferred to have the same signification under a Greek word, by that of the '*principe oxygine*.'"

In none of the memoirs after that of Easter 1775 is the claim for participation more than implied; it is made explicitly for the first time in the paper "On the Method of Increasing the Action of Fire," printed in the *Mémoires de l'Académie* for 1782, and in these words:—"It will be remembered that at the meeting of Easter 1775 I announced the discovery, which I had made some months before with M. Trudaine,[1] in the laboratory at Montigny, of a new kind of air, up to then absolutely unknown, and which we obtained by the reduction of *mercurius precipitatus per se*. This air, which Mr. Priestley discovered at very nearly the same time as I, and I believe even before me, and which he had procured mainly from the combination of minium

[1] M. Trudaine de Montigny died in 1777.

and of several other substances with nitric acid, has been named by him *dephlogisticated air*."

In the "Traité Elémentaire de Chimie" the claim for participation is again asserted in these words: "This air, which Mr. Priestley, Mr. Scheele, and I discovered at about the same time . . ."

Now, there is no question that Lavoisier knew of the existence of oxygen some months before he made the experiments with the burning-glass of M. Trudaine at Montigny, *for the simple reason that Priestley had already told him of it.* Priestley left Leeds in 1773 to become the librarian and literary companion of Lord Shelburne, and in the autumn of 1774 he accompanied his lordship on to the Continent, and spent the month of October in Paris. Lavoisier was famous for his hospitality; his dinners were celebrated; and Priestley, in common with every foreign *savant* of note who visited Paris at that period, was a welcome guest. What followed is best told in Priestley's own words:—"Having made the discovery [of oxygen] some time before I was in Paris, in the year 1774, I mentioned it at the table of Mr. Lavoisier, when most of the philosophical people of the city were present, saying that it was a kind of air in which a candle burnt much better than in common air, but I had not then given it any name. At this all the company, and Mr. and Mrs. Lavoisier as much as any, expressed great surprise. I told them I had gotten it from *precipitate per se* and also from *red lead.* Speaking French very imperfectly, and being little acquainted with the terms of chemistry, I said *plombe rouge*, which was not understood till Mr. Macquer said I must mean *minium.*"

In his account of his own work on dephlogisticated air, given in his "Observations," &c., 1790 edition, he further says, vol. ii. p. 108: "Being at Paris in the October following [the August of 1774], and knowing that there were several very eminent chemists in that place, I did not omit the opportunity, by means of my friend Mr. Magellan,[1] to get an ounce of *mercurius calcinatus* prepared by Mr. Cadet, of the genuineness of which there could not possibly be any suspicion; and, at the same time, I frequently mentioned my surprise at the kind of air which I had got from this preparation to Mr. Lavoisier, Mr. le Roy, and several other philosophers, who honoured me with their notice in that city, and who, I dare say, cannot fail to recollect the circumstance."

any further evidence is required to prove that Lavoisier was not only not "the true and first discoverer" of oxygen, but that he has absolutely no claim to be regarded even as a later and independent discoverer, it is supplied by M. Berthelot himself. Not the least valuable portion of M. Berthelot's book, as an historical work, is that which he devotes to the analysis of the thirteen laboratory journals of Lavoisier, which have been deposited, by the pious care of M. de Chazelles, his heir, in the archives of the Institute. M. Berthelot has given us a synopsis of the contents of almost every page of these journals, with explanatory remarks and dates when these could be ascertained. As he well says, these journals "are of great interest because they inform us of Lavoisier's methods of work and of the direction of his mind—I mean the successive steps in the evolution of his private thought." On the fly-leaf of the third journal is written "*du 23 Mars, 1774, au 13 février, 1776.*" From p. 30 we glean that Lavoisier visited his friend M. Trudaine at Montigny about ten days after his conversation with Priestley, and repeated the latter's experiments on the marine acid and alkaline airs (hydrochloric acid gas and ammonia). He is again at Montigny some time between February 28 and March 31, 1775, and repeats not only Priestley's experiments on the decomposition of mercuric oxide, presumably by means of M. Trudaine's famous burning-glass, but also his observations on the character of the gas. The fly-leaf of the fourth journal informs us that it extends from February 13, 1776, to March 3, 1778. On p. 1 is an account of experiments made February 13 on "précipité *per se* de chez M. Baumé," in which the disengaged gas is spoken of as "*l'air déphlogistique de M. Prisley*" (*sic*). Such a phrase in a private notebook is absolutely inconsistent with the idea that at this time Lavoisier considered himself as an independent discoverer of the gas. How he came to regard himself as such we need not inquire. Nor is it necessary to occupy your time by any examination of the arguments by which M. Berthelot, with the skill of a practised advocate, would seem to identify himself with the case of his client. We would do him the justice of recognizing the difficulty of his position. He seeks to discharge an obligation of which the acknowledgment has been too long delayed. The Académie des Sciences a year ago awoke to the sense of its debt of gratitude to the memory of the man who had laboured so zealously for its honour, and even for its existence, during the stormy period of which France has just celebrated the centenary, and out of the *éloge* on Lavoisier which M. Berthelot, as Perpetual Secretary, was commissioned to deliver, has grown "La Révolution Chimique." To write eulogy, however, is not necessarily to write history. We cannot but think that M. Berthelot has been hampered by his position, and that his opinion, or at least the free expression of it, has been fettered by the conditions under which he has written. We imagine we discern between the lines the consciousness that, to use Brougham's phrase, the brightness of the illustrious career which he eulogizes is dimmed with spots which a regard for historical truth will not permit him wholly to ignore.

[1] Prof. Grimaux ("Lavoisier," p. 51), says: "Un de ses [Lavoisier's] amis qui habitait Londres, Magalhaens ou Magellan, de la famille du célèbre navigateur, lui envoyait tous les mémoires sur les sciences qui paraissaient en Angleterre, et le tenait au courant des découvertes de Priestley."

Two cardinal facts made the downfall of phlogiston complete—the discovery of oxygen, and the determination of the compound nature of water. M. Berthelot's contention is that not only did Lavoisier effect the overthrow, but he also discovered the facts. In other words, he has not only a claim to a participation in the discovery of oxygen, but he is also "the true and first discoverer" of the non-elementary nature of water. This second claim is directly and explicitly stated. Although it is supported by a certain ingenuity of argument, we venture to think that we shall be able to show it has no greater foundation in reality than the first.

Members of the British Association, who are at all familiar with its history, will recall the fact that this is not the first occasion on which the attempt to transfer "those laurels which both time and truth have fixed upon the brow of Cavendish" has had to be resisted. At the Birmingham meeting of 1839 the Rev. W. Vernon Harcourt, who then presided, devoted a large portion of his address to an able and eloquent vindication of Cavendish's rights. The attack came then as now from the Perpetual Secretary of the French Academy, and the charges were also formulated then, as now, in an *éloge* read before that learned body. The assailant was M. Arago, who did battle, not for his countryman, Lavoisier, whose claims are dismissed as "pretensions," but on behalf of James Watt, the great engineer, who was one of the foreign members of the Institute.

It is not my wish to trouble you at any length with the details of what has come to be known in the history of scientific discovery as the Water Controversy—a controversy which has exercised the minds and pens of Harcourt, Whewell, Peacock, and Brougham in England; of Brewster, Jeffrey, Muirhead, and Wilson in Scotland; of Kopp in Germany; and of Arago and Dumas in France. This controversy, it has been said, takes its place in the history of science side by side with the discussion between Newton and Leibnitz concerning the invention of the Differential Calculus, and that between the friends of Adams and Leverrier in reference to the discovery of the planet Neptune. Up to now it has practically turned upon the relative merits of Cavendish and Watt. M. Berthelot is the first French *savant* of any note who has seriously put forward the claims of Lavoisier, his countryman and predecessor Dumas having deliberately rejected them.

At the risk of wearying you with detail, I am under the necessity of restating the facts in order to make the position clear. Some time before April 18, 1781, Priestley made what he called "a random experiment" for the entertainment of a few philosophical friends. It consisted in exploding a mixture of inflammable air (presumably hydrogen) and common air, contained in a closed glass vessel, by the electric spark, in the manner first practised by Volta in 1776. The experiment was witnessed by Mr. John Warltire, a lecturer on natural philosophy and a friend of Priestley, who had rendered him the signal service of giving him the sample of the mercuric oxide from which he had first obtained oxygen. Warltire drew Priestley's attention to the fact that after the explosion the sides of the glass vessel were bedewed with moisture. Neither of the experimenters attached any importance to the circumstance at the time, Priestley being of opinion that the moisture was pre-existent in the gases, as no special pains were taken to dry them. Warltire, however, conceived the notion that the experiment would afford the means of determining whether heat was ponderable or not, and hence he was led to repeat it, firing the mixture in a copper vessel for

greater safety. The results of these observations are contained in Priestley's "Experiments and Observations on Air," vol. v. 1781, App., p. 395.

At this period Cavendish was engaged on a series of experiments "made, as he says, principally with a view to find out the cause of the diminution which common air is well known to suffer by all the various ways in which it is phlogisticated, and to discover what becomes of the air thus lost or condensed" (Cavendish, Phil. Trans. 1784, p. 119). On the publication of Priestley's work he repeated Waltire's experiment, for, he says, as it "seemed likely to throw great light on the subject I had in view, I thought it well worth examining more closely." The series of experiments which Cavendish was thus induced to make, and which he made with all his wonted skill in quantitative work, led him some time in the summer of 1781 to the discovery that a mixture of two volumes of the inflammable air from metals (the gas we now call hydrogen) with one volume of the dephlogisticated air of Priestley combine together under the influence of the electric spark, or by burning, to form the same weight of water. If Cavendish had published the results of these observations at or near the time he obtained them, there would have been no Water Controversy. But in the course of the trials he found that the condensed water was sometimes acid, and the search for the cause of the acidity (which incidentally led to the discovery of the composition of nitric acid) occasioned the delay. The main result that a mixture of two volumes of inflammable air and one volume of dephlogisticated air could be converted into the same weight of water was, however, communicated to Priestley, as he relates in a paper in the Phil. Trans. for 1783. Priestley was at this time interested in an investigation on the seeming convertibility of water into air, and he was led to repeat Cavendish's experiments, some time in March 1783, on what was apparently the converse problem. Priestley, however, made a fatal blunder in the repetition. With the praiseworthy idea of obviating the possibility of any moisture in the gases, he prepared the dephlogisticated air from nitre, and the inflammable air by heating what he calls "perfectly made charcoal" in an earthenware retort. At this time, it must be remembered, there was no sharp distinction between the various kinds of inflammable air: hydrogen, sulphuretted hydrogen, marsh gas and olefiant gas, coal gas, the vapours of ether and turpentine, and the gas from heated charcoal, consisting of a mixture of carbonic oxide, marsh gas, and carbonic acid, were indifferently termed "inflammable air." Priestley attempted to verify Cavendish's conclusion on the identity of the weight of the gases used with that of the water formed; but his method in this respect, as in his choice of the inflammable air, was wholly defective, and could not possibly have given him accurate results. It consisted in wiping out the water from the explosion vessel by means of a weighed piece of blotting-paper and determining the increase of weight of the paper. He says, however:—"I always found as near as I could judge the weight of the decomposed air in the moisture acquired by the paper. . . . I wished, however, to have had a nicer balance for this purpose; the result was such as to afford a strong presumption that the air was reconverted into water, and therefore that the origin of it had been water." These results, together with those on the conversion of water into air, were communicated towards the end of March 1783 by Priestley to Watt, who began to theorize upon them, and then to put his thoughts together in the form of a letter to Priestley, dated April 26, 1783, and which he requested might be read to the Royal Society on the occasion of the presentation of Priestley's memoir. In this letter Watt says:—"Let us now consider what obviously happens in the case of the deflagration of the inflammable and dephlogisticated air. These two kinds of air unite with violence, they become red-hot, and upon cooling totally disappear. When the vessel is cooled, a quantity of water is found in it equal to the weight of the air employed. This water is then the only remaining product of the process, and *water, light,* and *heat* are all the products. *Are we not then authorized to conclude that water is composed of dephlogisticated air and phlogiston deprived of part of their latent or elementary heat; that dephlogisticated or pure air is composed of water deprived of its phlogiston and united to elementary heat and light, &c.?*"

This letter, although shown to several Fellows of the Society, was not publicly read at the time intended. Priestley, before its receipt, had detected the fallacy of his experiments on the seeming conversion of water into air, and as much of the letter was concerned with this matter Watt requested that it should be withdrawn. Watt, however, as he tells Black[1] in a letter dated June 23, 1783, had not given up his theory as to the nature of water, and on November 26, 1783, he restated his views more fully in a letter to De Luc. In the meantime, Cavendish, having completed one section of his investigation, sent in a memoir to the Royal Society, which was read on January 15, 1784, in which he gives an account of his experiments, and announces his conclusion "that dephlogisticated air is in reality nothing but dephlogisticated water, or water deprived of its phlogiston; or, in other words, that water consists of dephlogisticated air united to phlogiston; and that inflammable air is either pure phlogiston, as Dr. Priestley and Mr. Kirwan suppose, or else water united to phlogiston." Watt thereupon requested that his letter to De Luc should be published, and it was accordingly read to the Royal Society on April 29, 1784. Which of the two—Cavendish or Watt—is, under these circumstances, to be considered as "the true and first discoverer" of the compound nature of water is the question which has been hitherto the main subject of the Water Controversy.

Let us now consider the matter as it affects Lavoisier. In 1783, Lavoisier had publicly declared against the doctrine of phlogiston, or rather, as M. Dumas puts it, "against the crowd of entities of that name which had no quality in common except that of being intangible by every known method" ("Leçons sur la Philosophie Chimique," p. 161). How completely Lavoisier had dissociated himself from the theory may be gleaned from his memoir of that year. "Chemists," he says, "have made a vague principle of phlogiston which is not strictly defined, and which in consequence accommodates itself to every explanation into which it is pressed. Sometimes this principle is heavy and sometimes it is not; sometimes it is free fire and sometimes it is fire combined with the earthly element; sometimes it passes through the pores of vessels and sometimes they are impenetrable to it: it explains at once causticity and non-causticity, transparency and opacity, colours and the absence of colours. It is a veritable Proteus which changes its form every moment."

But Lavoisier had merely renounced one fetich for another. At the time that he penned these lines he was as much under the thraldom of *le principe oxygine* as the most devoted follower of Stahl was in the bondage of phlogiston. The idea that the calcination of metals was but a slow combustion had been fully recognized. M. Berthelot tells us that, as far back as the March of 1774, Lavoisier had written in his laboratory journal:—"I am persuaded that the inflammation of inflammable air is nothing but a fixation of a portion of the atmospheric air, a decomposition of air. . . . In that case in every inflammation of air there ought to be an increase of weight, and he tried to ascertain this by burning hydrogen at the mouth of a vessel from which it was being disengaged. In the following year he asks, What remains when inflammable air is burnt completely? According to the theory by which he is now swayed it should be an acid, and he made many attempts to capture this acid. In 1777 he and Bucquet burnt six pints of the inflammable air from metals in a bottle containing lime-water, in the expectation that fixed air would be the result. And in 1781 he repeated the experiment with Gengembre, with the modification that the oxygen was caused to burn in an atmosphere of hydrogen, but not a trace of any acid product could be detected. Of course there must have been considerable quantities of water formed in these experiments, but Lavoisier was preoccupied with the conviction that oxidation meant acidification, and its presence was unnoticed, or, if noticed, was unheeded. Macquer, in 1776, had drawn attention to the formation of water during the combustion of hydrogen in air, but Lavoisier has stated that he was ignorant of that observation. What was it then that put him on the right track? We venture to think that M. Berthelot has himself supplied the answer. He says (p. 114):—"Rumours of Cavendish's trials had spread throughout the scientific world during the spring of 1783. . . . Lavoisier, always on the alert as to the nature of the products of the combustion of hydrogen, was now in such position that the slightest hint would enable him to comprehend its true nature. He hastened to repeat his trials, as he had the right to do, never having ceased to occupy himself with a question which lay at the very heart of his doctrine."

"On the 24th of June, 1783," continues M. Berthelot, "he repeated the combustion of hydrogen in oxygen, and he obtained a notable quantity of water without any other product, and he

[1] Watt, "Correspondence," p. 31.

concluded from the conditions under which he had worked that the weight of the water formed could not be other than equal to that of the two gases which had formed it. The experiment was made in the presence of several men of science, among whom was Blagden, a member of the Royal Society of London, who on *this occasion* recalled the observations of Cavendish (*qui rappela à cette occasion les observations de Cavendish*)."

On the following day Lavoisier published his results. The following is the official minute of the communication taken from the register of the sittings of the Académie des Sciences :—

Meeting of Wednesday, June 25, 1783.

MM. Lavoisier and De Laplace announced that they had lately repeated the combustion of Combustible Air with Dephlogisticated Air; they worked with about 60 pints of the airs, and the combustion was made in a closed vessel: the result was very pure water.

The cautious scribe who penned that minute did not commit himself too far. M. Berthelot, however, regards it as the first certain date of publication, established by authentic documents, in the history of the discovery of the composition of water; "a discovery," he adds, "which, on account of its importance, has excited the keenest discussion."

You will search in vain through the laboratory journals, as given by M. Berthelot, for any indications either of experiments or reflections which would enable you to trace the course of thought by which Lavoisier was guided to the truth. There is absolutely nothing on the subject until in the eighth volume (25 *mars*, 1783, *au février* 1784), and on p. 63 we come to the experiment of June 24, and we read :—"In presence of Messieurs Blagden, of [name illegible], de Laplace, Vandermonde, de Fourcroy, Meusnier, and Legendre, we have combined in a bell-jar dephlogisticated air and inflammable air drawn from iron by means of sulphuric acid, &c. . . . The amount of water may be estimated at 3 drachms: the amount which should have been obtained was 1 ounce 1 drachm and 12 grains. Thus we must suppose that there was a loss of two-thirds of the amount of the air or that there has been a loss of weight."

And this is the experiment which, according to M. Berthelot, enabled Lavoisier to conclude that "the weight of the water formed could not be other than equal to that of the two gases which had formed it"! It is on this single experiment, hurriedly and imperfectly done, that Lavoisier's claim to the discovery of the compound nature of water is based! M. Berthelot objects to the assumption that it was hurriedly done. He says, on p. 114: "Lavoisier caused a new apparatus to be made, with a couple of tubes and two reservoirs for the gases, an arrangement which would require a certain amount of time to put together; this circumstance proves that it could not have been an improvised trial." To what extent it was improvised will be seen immediately.

Now although the laboratory journals do not in this case "inform us of Lavoisier's methods, and of the direction of his mind, . . . the successive steps in the evolution of his private thought," we have other means of ascertaining how he arrived at his knowledge. The method was simplicity itself: he *was told of the fact, and his informant was none other than Cavendish's assistant, Blagden.*

Cavendish's memoir was published in 1784. Before it was struck off its author caused the following addition to be made: "During the last summer also a friend of mine gave some account of them [the experiments] to M. Lavoisier, as well as of the conclusion drawn from them, that dephlogisticated air is only water deprived of phlogiston; but at that time so far was M. Lavoisier from thinking any such opinion warranted that, till he was prevailed upon to repeat the experiment himself, he found some difficulty in believing that nearly the whole of the two airs could be converted into water." This addition, as I have had the opportunity of verifying by an inspection of the original MSS. in the archives of the Royal Society, was made in the handwriting of Cavendish's assistant and amanuensis, Blagden.

When Lavoisier's memoir appeared, it was found to contain the following reference to this circumstance:—"It was on the 24th June that M. de Laplace and I made this experiment in presence of MM. le Roi, Vandermonde, and several other Academicians, and of Mr. Blagden, the present Secretary of the Royal Society of London. The latter informed us (*ce dernier nous apprit*) that Mr. Cavendish had already tried, in London, to burn inflammable air in closed vessels, and that he had obtained a very sensible quantity of water."

This reference was so partial, and its meaning so ambiguous, that Blagden addressed the following letter to Crell to be published in his *Chemische Annalen* (Crell's *Annalen*, 1786, vol. i. p. 58).

It is so direct and conclusive that I offer no apology for giving it almost entire :—[1]

"I can certainly give you the best account of the little dispute about the first discoverer of the artificial generation of water, as I was the principal instrument through which the first news of the discovery that had been already made was communicated to Mr. Lavoisier. The following is a short statement of the history :—

"In the spring of 1783, Mr. Cavendish communicated to me, and other members of the Royal Society, his particular friends, the result of some experiments with which he had for a long time been occupied. He showed us that out of them he must draw the conclusion that dephlogisticated air was nothing else than water deprived of its phlogiston; and, *vice versâ*, that water was dephlogisticated air united with phlogiston. About the same time the news was brought to London that Mr. Watt, of Birmingham, had been induced by some observations to form a similar opinion. Soon after this I went to Paris, and in the company of Mr. Lavoisier and of some other members of the Royal Academy of Sciences I gave some account of these new experiments and of the opinions founded upon them. They replied that they had already heard something of these experiments, and particularly that Dr. Priestley had repeated them. They did not doubt that in such manner a considerable quantity of water might be obtained, but they felt convinced that it did not come near to the weight of the two species of air employed, on which account it was not to be regarded as water formed or produced out of the two kinds of air, but was already contained in and united with the airs, and deposited in their combustion. This opinion was held by Mr. Lavoisier, as well as by the rest of the gentlemen who conferred on the subject; but, as the experiment itself appeared to them very remarkable in all points of view, they unanimously requested Mr. Lavoisier, who possessed all the necessary preparations, to repeat the experiment, on a somewhat larger scale, as early as possible. This desire he complied with on June 24, 1783 (as he relates in the latest volume of the Paris memoirs). From Mr. Lavoisier's own account of his experiment, it sufficiently appears that at that period he had not yet formed the opinion that water was composed of dephlogisticated and inflammable airs, for he expected that a sort of acid would be produced by their union. In general, Mr. Lavoisier cannot be convicted of having advanced anything contrary to truth; but it can still less be denied that he concealed a part of the truth; for he should have acknowledged that I had, some days before, apprised him of Mr. Cavendish's experiments, instead of which the expression 'il nous apprit' gives rise to the idea that I had not informed him earlier than that very day. In like manner Mr. Lavoisier has passed over a very remarkable circumstance—namely, that the experiment was made in consequence of what I had informed him of. He should likewise have stated in his publication not only that Mr. Cavendish had obtained 'une quantité d'eau très sensible,' but that the water was equal to the weight of the two airs added together. Moreover, he should have added that I had made him acquainted with Messrs. Cavendish and Watt's conclusions—namely, that water, and not an acid, or any other substance, arose from the combustion of the inflammable and dephlogisticated airs. But *those* conclusions opened the way to Mr. Lavoisier's present theory, which perfectly agrees with that of Mr. Cavendish, only that Mr. Lavoisier accommodates it to his old theory, which banishes phlogiston. . . . The course of all this history will clearly convince you that Mr. Lavoisier (instead of being led to the discovery by following up the experiments which he and Mr. Bucquet had commenced in 1777) was induced to institute again such experiments, solely by the account he received from me, and of our English experiments; and that he really discovered nothing but what had before been pointed out to him to have been previously made out and demonstrated in England."

[1] Mr. Muirhead's translation. *Vide* Watt, "Correspondence," "Composition of Water," p. 71.

To this letter, reflecting so gravely on his honour and integrity, Lavoisier made no reply. Nor did Laplace, Le Roi, Vandermonde, or any one of the Academicians concerned, vouchsafe any explanation. *De non apparentibus et de non existentibus eadem est ratio.* No explanation appeared, because none was possible. M. Berthelot ignores this letter, which is the more remarkable, since reference is made to it in more than one of the publications which he tells us he has consulted in the preparation of his account of the Water Controversy. If he knew of it he must regard it either as unworthy of an answer or as unanswerable.

It would be heaping Ossa on Pelion to adduce further evidence from letters of the time of what Lavoisier's contemporaries thought of his claims. *De mortuis nil nisi bonum.* I would much more willingly have dwelt upon the virtues of Lavoisier, and have let his faults lie gently on him; but I have felt it incumbent on me on this occasion to make some public answer to M. Berthelot's book, and in no place could that answer be more fittingly given than in this town, which saw the dawn of that work out of which these grand discoveries arose. It may be that much of what I have had to say is as a twice-told tale to many of you. I trust I need make no apology on that account. The honour of our ancestors is in our keeping, and we should be unworthy of our heritage and false to our trust if we were slow to resent or slack to repel any attempt to rob them of that glory which is their just right and our proud boast.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY A. H. GREEN, M.A., F.R.S., PROFESSOR OF GEOLOGY IN THE UNIVERSITY OF OXFORD, PRESIDENT OF THE SECTION.

THE truth must be told; and this obliges me to confess that my contributions to our stock of geological knowledge, never very numerous, have of late years been conspicuously few, and so I have nothing to bring before the Geelogical Section that can lay any claim to be the result of original research.

In fact, nearly all my time during the last fifteen years has been taken up in teaching. This had led me to think a good deal about the value of geology as an educational instrument, and how its study compares with that of other branches of learning in its capability of giving sinew and fibre to the mind, and I have to ask you to listen to an exposition of the notions that have for a long time been taking shape bit by bit in my mind on this subject.

I am not going to enter into the question, handled repeatedly and by this time pretty well threshed out, of the relative value of natural science, literature, and mathematics, as a means of educational discipline; for no one who is lucky enough to know a little of all three will deny that each has an importance of its own, and its own special place in a full and perfect curriculum. The question which is the most valuable of the three I decline to entertain, on the broad general ground that "comparisons are odorous," and for the special reason that the answer must depend on the constitution of the mind that is to be disciplined. I might quite as reasonably attempt to lay down that a certain diet which suits my constitution and mode of life must agree equally well with all that hear me.

I need scarcely say that nothing would induce me, if it could possibly be helped, to say one word that might tend to disparage the pursuit to which we are all so deeply attached. But I cannot shut my eyes to the fact that, when geology is to be used as a means of education, there are certain attendant risks that need to be carefully and watchfully guarded against.

Geologists, and I do not pretend myself to be any better than the rest of them, are in danger continually of becoming loose reasoners. I have often had occasion to feel this, and I recall a scene which brought it home to me most forcibly. At a gathering, where several of our best English geologists were present, the question of the cause of changes of climate was under discussion. The explanation which found most favour was a change of the position of the axis of rotation within the earth itself; and this, it was suggested, might have been brought about by the upheaval of great bodies of continental and mountainous land where none now exist, and an accompanying depression of the existing continents or parts of them. That such a redistribution of the heavier material of the earth would result in some shifting of the axis of rotation admits of no doubt. The important question is, How much? What degree of rearrangement of land and sea would be needed to produce a shift of the amount required? It is purely a question of figures, and the necessary calculations can be made only by a mathematician. I ventured to suggest that some one who could work out the sum should be consulted before a final decision was arrived at, for I knew perfectly well that not one of the company present could do it. But if I say that my advice met with scant approval, I should represent very inadequately the lack of support I met with. The bulk of those present seemed quite content with the vague feeling that the thing could be done in the way suggested, and there was a general air of indifference as to whether the hypothesis would stand the test of numerical verification or not.

I could bring many other similar instances which seem to me to justify the charge I have ventured to make; but it will be more useful to inquire what it is that has led to a failing, which, if it really exist, must be a source of regret to the whole brotherhood of hammerers.

The reason, I think, is not far to seek. The imperfection of the Geological Record is a phrase as true as it is hackneyed. No more striking instance of its correctness can be found than that furnished by the well-known mammalian jaws from the Stonesfield slate. The first of these was unearthed about 1764; others, to the number of some nine, between then and 1818. The rock in which these precious relics of the beginning of mammalian life occur has been quarried without intermission ever since; it has been ransacked by geologists and collectors without number; many of the quarrymen know a jaw when they see it, and are keenly alive to the market value of a specimen; but not one of these prized and eagerly-sought-after fossils has turned up during the last seventy years.

Then, again, how many of the geological facts which we gather from observation admit of diverse explanation. Take the case of *Eozoon Canadense*. Here we have structures which some of the highest authorities on the Foraminifera assure us are the remains of an organism belonging to that order; other naturalists, equally entitled to a hearing, will have it that these structures are purely mineral aggregates simulating organic forms. And hereby hangs the question whether the limestones in which the problematical fossil occurs are organic, or formed in some other and perhaps scarcely explicable way.

And this after all is only one of the countless uncertainties that crowd the whole subject of invertebrate palæontology. In what a feeble light have we constantly to grope our way when we attempt the naming of fossil Conchifers for instance. The two species *Gryphæa dilatata* and *G. bilobata* furnish an illustration. Marked forms are clearly separable, but it is easy to obtain a suite of specimens, even ftom the Callovian of which the second species is said to be specially characteristic, showing a gradual passage from one form into the other. And over and over again the distinctions relied upon for the discrimination of species must be pronounced far-fetched and shadowy, and are, it is to be feared, often based upon points which are of slender value for classificatory purposes. In the case of fossil plants the last statement is notoriously true, and yet we are continually supplied with long lists of species which every botanist knows to be words and nothing more, and zonal divisions are based upon these bogus species and conclusions drawn from them.

It is from data such as have been instanced, scrappy to the last degree, or from facts capable of being interpreted in more than one way, or from determinations shrouded in mist and obscurity, that we geologists have in a large number of cases to draw our conclusions. Inferences based on such incomplete and shaky foundations must necessarily be very largely hypothetical. That this is the character of a great portion of the conclusions of geology we are all ready enough to allow with our tongue—nay, even to lay stress upon the fact with penned or spoken emphasis. But it is open to question whether this homage at the shrine of logic is in many cases anything better than lip-service; whether we take sufficiently to heart the meaning of our protestations, and are always as alive as our words would imply to the real nature of our inferences.

A novice in trade, scrupulously honest, even morbidly conscientious to begin with, if he lives among those who habitually use false scales, runs imminent risk of having his sense of integrity unconsciously blunted and his moral standard insensibly lowered. A similar danger besets the man whose life is occupied in deducing tentative results from imperfectly ascertained facts. The living, day by day, face to face with approximation and conjecture must tend to breed an indifference to

accuracy and certainty, and to abate that caution and that wholesome suspicion which make the wary reasoner look well to his foundations, and resolutely refuse to sanction any superstructures, however pleasing to the eye, unless they are firmly and securely based.

If I am right in thinking that the mental health of the geologist of matured experience and full-grown powers is liable to a disorder of the kind I have indicated, how much greater must the risk be in the case of a youth, in whom the reasoning faculty is only beginning to be developed, when he approaches the study of geology! And does it not seem at first sight that that study could scarcely be used with safety as a tool to shape his mind, and so train his bent that he shall never even have a wish to turn aside either to the right hand or to the left from the strait path that leads through the domain of sound logic?

That it is hazardous, and that evil may result from an incautious use of geology as an educational tool, I entertain no doubt. The same may, indeed, be said of many other subjects, but I feel that it is specially true in the case of geology. But I should be guilty of that very haste in drawing conclusions against which I am raising a warning word, if I therefore inferred that geology can find no place in the educational curriculum.

To be forewarned is a proverbial safeguard, and those who are alive to a danger will cast about for a means of guarding against it. And there are many ways of neutralizing whatever there may be potentially hurtful in the use of geology for educational ends. It has been said that the right way to make a geologist is not to teach him any geology at all to begin with. To send him first into a laboratory, give him a good long spell at observations and measurements requiring the minutest accuracy, and so saturate his mind with the conception of exactness that nothing shall ever afterwards drive it out. If a plan like this be adopted, it is easy to pick out such kinds of practical work as will not only breed the mental habits aimed at, but will also stand him in good stead when he goes on to his special subject. Goniometrical measurements and quantitative analysis will serve the double purpose of inspiring him with accurate habit of thought, and helping him to deal with some of the minor problems of geology. And I cannot hold that this practice of paying close attention to minute details will necessarily unfit a man for taking wider sweeps and more comprehensive views later on. That habit comes naturally to every man who has the making of a geologist in him directly he gets into the field. Put such a man where a broad and varied landscape lies before him, teach him how each physical feature is the counterpart of geological structure, and breadth of view springs up a native growth. I do not mean to say that the plan just suggested is the only way of guarding against the risk I have been dwelling upon. There are many others. This will serve as a sample to show what I think ought to be aimed at in designing the geological go-cart. And any such mind-moulding leads, be assured, not to hesitancy and doubt, but to conclusions, reached slowly it may be, but so securely based that they will seldom need reconstruction.

There is another aspect of the question. The uncertainties with which the road of the geologist are so thickly strewn have an immense educational value, if only we are on our guard against taking them for anything better than they really are. Of those stirring questions which are facing us day by day and hour by hour, none perhaps is of greater moment than the discussion of the value of the evidence on which we base the beliefs that rule our daily life. A man who is ever dealing with geological evidence and geological conclusions, and has learned to estimate these at their real value, will carry with him, when he comes to handle the complex problems of morals, politics, and religion, the wariness with which his geological experience has imbued him.

Now I trust the prospect is brightening. Means have been indicated of guarding against the danger which may attend the use of geology as an educational instrument. Need I say much to an audience of geologists about the immense advantages which our science may claim in this respect? In its power of cultivating keenness of eye it is unrivalled, for it demands both microscopic accuracy and comprehensive vision. Its calls upon the chastened imagination are no less urgent, for imagination alone is competent to devise a scheme which shall link together the mass of isolated observations which field work supplies; and if, as often happens, the fertile brain devises several possible schemes, it is only where the imaginative faculty has been kept in check by logic that the one scheme that best fits each case will be selected for final adoption. But, above all, geology has its home, not in the laboratory or study, but *sub Jove*, beneath the open sky; and its pursuit is inseparably bound up with a love of Nature, and the healthy tone which that love brings alike to body and mind.

And what does the great prophet of Nature tell us about this love?

> "The boy beholds the light and whence it flows;
> The man perceives it die away,
> And fade into the light of common day."

Will it not, then, be kind to encourage the boy to follow a pursuit which will keep alive in him a joy which years are too apt to deaden; and will not the teaching of geology in schools conduce to this end? Geology certainly should be taught in schools, and for more prosaic reasons, of which the two following are, perhaps, the most important. Geography is essentially a school subject, and the basis of all geographical teaching is physical geography. This cannot be understood without constant reference to certain branches of geology. Again, how many are the points of contact between the history of nations, the distribution and migrations of peoples, and the geological structures of the lands they have dwelt in or marched over.

But geology is not an easy subject to teach in schools. The geology of the ordinary text-book does not commend itself to the boy-mind. The most neatly-drawn sections, nay, even the most graphic representations of gigantic and uncouth extinct animals, come home to the boy but little, because they are pictures and not things. He wants something that he can handle and pull about; he does not refuse to use his head, but he likes to have also something that will employ his hands at the same time.

The kind of geology that boys would take to is outdoor work; and, of course, where it can be had, nothing better could be given them. A difficulty is that field work takes time and filches away a good deal of the intervals that are devoted to games. Still cross-country rambles and scrambling about quarries and cliffs are not so very different from a paper-chase; and if the teacher will only infuse into the work enough of the fun and heartiness which come so naturally in the open air, he need not despair of luring even the most high-spirited boy, every now and then, away from cricket and football.

But there are localities not a few—the Fen country, for instance—where it is scarcely possible to find within manageable distance of the school the kind of field-geology which is within the grasp of a beginner. But even here the teaching need not be wholly from books. The best that can be done in such cases is to make object-lessons indoors its basis. For instance, give a lad a lump of coarsish sandstone; let him pound it and separate by elutriation the sand grains from the clay; boil both in acid, and dissolve off the rusty coating that colours them; ascertain by the microscope that the sand grains are chips and not rounded pellets, and so on. All such points he will delight to worry out for himself; and, when he has done that, an explanation of the way in which the rock was formed will really come home to him. Or it is easy to rig up contrivances innumerable for illustrating the work of denudation. A heap of mixed sand and powdered clay does for the rock denuded; a watering-can supplies rain; a trough, deeper at one end than the other, stands for the basin that receives sediment. By such rough apparatus many of the results of denudation and deposition may be closely imitated, and the process is near enough to the making of mud-pies to command the admiration of every boy. It is by means like these that even indoor teaching of geology may be made life-like.

I need not dwell upon the great facts of physical geology which have so important a bearing on geography and history; but I would, in passing, just note that these too often admit of experimental illustration, such for instance as the well-known methods of imitating the rock-folding caused by earth-movements. I would add that wherever, in speaking of school teaching, I have used the word "boy," that word must of course be taken to include "girl" as well.

In conclusion I should like to give you an outline of the kind of course I endeavour to adopt in more advanced teaching in the case of students who are working at other subjects as well, and can give only a part of their time to geology. During the first year the lectures and book-work should deal with physical geology. In the laboratory the student should first make the acquaintance of the commoner rock-forming minerals, the means of recognizing them by physical characters, blowpipe tests, and

the simpler methods of qualitative analysis, and may then go on to work at the commoner kinds of rocks and the elements of microscopic petrography. During the summer months I would take him into the field, but not do more than impress upon him some of the broader aspects of outdoor work, such as the connection between physical feature and geological structure.

During a second year stratigraphical geology should be lectured upon and studied from books, and so much of animal morphology as may be necessary for palæontological purposes should be mastered. The practical work would lie mainly among fossils, with a turn every now and again at mineralogy and petrology to keep these subjects going. Out of doors I would not yet let the student attempt geological mapping, but would put into his hands a geological map and descriptions of the geology of his neighbourhood, and he would be called upon to examine in minute detail all accessible sections, collect and determine fossils, and generally see how far he can verify by his own work the observations of those who have gone before him.

Indoor work during the third year would be devoted to strengthening and widening the knowledge already gained. Out of doors the student should attempt the mapping of a district by himself. It will be well, if there is any choice in the matter, to select one in which the physical features are strongly marked.

This sketchy outline must serve to indicate the notions that have grown up in my mind on the subject now before us, and the methods I have been led to adopt in the teaching of geology. I trust that they may be suggestive, and may call forth that kindly and genial criticism with which the brotherhood of the hammer are wont to welcome attempts, however feeble, to strengthen the corner-stones and widen the domain of the science we love so well, and to enlarge the number of its votaries.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

British Association Procedure.

I AM glad to see a letter from my colleague, Prof. Armstrong, on the subject of the procedure of the British Association. I am not disposed to take an exaggerated view of the harm that may arise from the mild excitement and dissipation which seem to be inseparable from gatherings of this kind; but I do not regard with satisfaction the prospect of annulling half the good effect of my much-needed rest and annual dose of fresh air, by spending a week in crowded rooms in the middle of a great town. The disinclination to run this risk increases, and the risk itself seems to increase, when the date fixed for the meeting is selected in such an unfortunate way as to cut in two the summer holiday of many members, and especially of those who are teachers, whether in school, college, or university.

Having been on two separate occasions concerned in making preparations for the reception of the Association, I know something of the circumstances which have to be considered. One of the most important points is the provision of suitable rooms for reception and Sectional business. These are very commonly obtained in colleges or schools, and cannot be placed at the disposal of the Association till the holidays begin. But all schools or colleges break up before the end of July, and the last days of July or the first days of August would be the most convenient time to the great majority of those who form the most numerous and active attendants at the meetings. The weather at that time is also more likely to be favourable to garden parties and excursions than at any time late in August or in September. That, at least, is my own opinion as to the time of meeting.

Then as to the work of the Sections. As a Sectional Secretary I have read papers (other people's) at 3 o'clock in the afternoon to an audience consisting of a Vice-President impatient to follow the President to lunch, two reporters who were not listening, and my wife making signals of distress from a back bench. As a Sectional President I have sat at the same hour, luncheonless and weary, while a paper which seemed as long and as discursive as the story of the Ancient Mariner, was droned forth by the author to an audience of about three persons fidgeting like the belated wedding guest. I wonder whether this sort of thing is supposed to be of any use to anybody.

The change which I proposed, and which was in part embodied in a recommendation from Section B to the Council, consisted in altering the hour for Committees from 10 to 9.30, and beginning general business at 10 instead of 11; the Section to close at 2.

The only objection I heard to 9.30 was that some members might be lodged at a distance, and find it difficult to attend so early. I never could see much except laziness at the bottom of this objection. The only other that occurred to me was that possibly sometimes the Committee business would occupy more than half an hour. But this difficulty, even if real, chiefly arises from the practice to which Prof. Armstrong has referred, of making the Committees so large.

This practice serves no obvious purpose except that of advertising a certain number of people who like to see their names in print. I believe the demand for election upon Sectional Committees would be considerably reduced if the names of the Sectional Committees *were no longer printed*. It would be quite sufficient for the purposes of business to give in the Journal only the names of the officers.

I think, further, that something should be done to reduce the cost of a meeting to the town visited by the Association. The gorgeousness of the entertainments given, and the demands made upon provincial pockets, have become so extravagant that none but wealthy or ambitious towns can face the luxury of a visit of the British Association. WILLIAM A. TILDEN.

Birmingham, September 1.

WHILST I entirely agree with Prof. Armstrong as to the desirability of reform in regard to most of the matters to which he has called attention, I would like to point out that in one respect the large Sectional Committees have perhaps served a useful purpose. Nowhere are the older and younger men of science brought so extensively into direct contact with each other as at the meetings of these Committees, and hence they have served perhaps more than anything else to introduce the younger provincial men to their older and younger brethren of the metropolis and to each other.

If it be admitted therefore that a chief object of the Association is that its members shall meet, I think, speaking as a provincial, that there is much to be said in favour of the retention of moderately large Sectional Committees; though no doubt the introduction of such reforms as would tend to discourage the presence on them of those who are out of place would add to their usefulness in every way. W. A. SHENSTONE.

Clifton, September 2.

Fine Group of Sun-spots.

THIS morning I saw a very large cluster of spots in the sun's northern hemisphere, and nearly at mid-transit across the disc. The group is elongated east and west, and there is a fine spot at each of the extremities. The length of the group is about 113,000 miles; it exhibits a very complicated structure, and I have made a drawing of it with some difficulty, owing to the rapid changes it is undergoing in detail. A 3-inch refractor, power 90, defines the object well, and reveals many peculiarities in its form. Though I have termed it a group of spots, it might with propriety be called a single spot, for it is connected with wisps of penumbra, and chains of small spots, which altogether represent an extensive area of disturbance.

On looking at the sun with the eye simply protected with tinted glass, I see the group of spots distinctly, and it would form quite a conspicuous appearance to the naked eye should the sun rise or set in a fog during the next day or two.

I ascertained by frequent scrutiny during the first half of the present year that the sun's spots were usually very small and fugitive, and the present fine display of *maculæ* is therefore all the more worthy of observation and record.

Bristol, August 31. W. F. DENNING.

Organic Colour.

IN considering the causes of bright colouring in animals and plants, I think the physical meaning of colour has not been sufficiently regarded.

All dull colours, such as browns, olives, plums, &c., mean that vibrations of every wave-length in the white sunlight are absorbed almost entirely, a very small proportion being reflected. A deep red colour means that there is a less proportion of the longest waves absorbed; a deep violet, that there is a less proportion of the shortest waves absorbed; and a full green, that the absorption is less in the intermediate wave-lengths. These are the primary hues; but in objects which reflect the brilliant secondary hues—scarlets, yellows, blues, and pinks—the chief absorption is confined to a small area in the spectrum, a large proportion of the light being reflected.

There are, then, three distinct stages of coloration, viz. (1) that in which all wave-lengths are absorbed; (2) that in which absorption ceases in respect to about one-third of the spectrum; (3) that in which absorption ceases in respect to about two-thirds of the spectrum.

These three stages are progressive, and in the direction of progress from chaos to unity; from a condition of the protoplasm in which molecular elements of very diverse vibrating capacity are mixed up together, to a condition in which the capacities of these elements have become greatly simplified.

When we speak of an organism arriving at maturity, we imply that it began its career in a state of immaturity, and that it gradually progresses to the condition of maturity. In what that condition consists, or what fundamental changes have taken place, it may not be easy to say; but it is surely true, as a rule, that organisms in an early and immature state are comparatively dull in colour, and do not put on their brightest hues until the period of maturity, indicating that one of the characteristics of maturity is the simplification of the vibrating capacity of the molecules. If this be really a law of Nature, it is a far-reaching one, and will account for much. F. T. MOTT.

Leicester.

On the Soaring of Birds.

I HAVE thought that this habit can be explained as follows; at least as regards rooks, which I have often noticed soaring in flocks, especially in the spring, and I think usually in warm cloudy weather.

An upward convection current of warm air is established over some area. The birds stretch out their wings, and if the upward velocity of the current should happen to be just equal to the velocity with which a bird with outstretched wings would sink through still air (the "terminal velocity"), the bird would be supported; but if it were somewhat greater, the bird would be raised upwards. In that case he inclines his wings so that the resolved part of the pressure on the under side of the wings carries him forward at a uniform level. But this movement, being rectilinear, would take him outside the warm column which he is enjoying. A centripetal force is therefore needed to maintain the circular movement, and this is obtained by tipping the wings, so that the wing which points outwards is raised, and that which points inwards towards the warm column is depressed, as noticed by your correspondent. If the upward velocity of the current is not sufficient to support the bird, an occasional flap with both wings, and the subsequent sinking, supplies the deficiency of upward pressure.

O. FISHER.

IN your issue of August 21 (p. 397) Mr. Magnus Blix gives a very ingenious explanation of the soaring of birds. It appears, however, to me that this explanation rests upon a false basis.

In his illustration, Mr. Blix supposes a bird to be moving in a direction, relative to the wind, at right angles to that of the wind, its absolute velocity, therefore, being greater than that of the wind. He then supposes the bird, by movement of wing-plane, to change its direction to one opposite to that of the wind, and assumes that its absolute velocity, in the new direction, will be equal to the absolute velocity in the old.

Now it is probably true that a bird can change its direction without sensible loss of *velocity relative to the air*, but any velocity it may have, in virtue of the motion of the air, must remain as a component of the new velocity in the same direction as before, however the bird may change the direction of its wing-plane.

Now the supposed bird, in changing its direction at *c*, would still have the component of velocity due to the wind acting in direction *ef* as before. Its velocity relative to the wind, therefore, from *c* to *d* would be the original velocity at *a* (diminished in its passage from *a* to *c*); its absolute velocity the difference of the two velocities.

If this objection hold good, Mr. Blix's theory seems to be no longer an explanation. C. O. BARTRUM.

19 Well Walk, Hampstead, August 26.

Occurrence of a Crocodile on Cocos Islands.

DURING a recent visit to Cocos Islands Mr. Ross showed me the skull of a crocodile of small size which had appeared about a year previously on the islands. It was first seen by a native Cocosian, who reported that he had seen something between a lizard and a log of wood in the sea. It then reappeared upon another island and destroyed a number of ducks, and was eventually shot by Mr. Ross. The distance from Java, the nearest land, is fully 700 miles. It is remarkable that this animal should have swum so far, and managed eventually to strike this small patch of land in the middle of the ocean. I do not know another record of a big reptile travelling so far. Mr. Ross tells me that bamboo-rafts sometimes drift to Cocos, and perhaps it managed to help itself along on one of these.

The whole seas here, but especially the Straits of Sunda and Malacca Straits, are full of drift-fruits, seeds, sticks, stems of Nipa and Pandanus; and between the Straits of Sunda and Cocos, large patches of pumice rolled lumps and dust can be seen, the relics of the destruction of Krakatão.

H. N. RIDLEY.

Botanic Gardens, Singapore, August 6.

Helix nemoralis and hortensis.

I SHOULD be very pleased if some of the various conchological readers of NATURE would kindly furnish me with their records of these two shells. The questions I specially want to ask concerning them are as follows:—What varieties (with band-formulæ) have they found? What number of each variety and band-variation have they taken? What is the environmental condition of the localities where they have found them, as regards plant-life and geological formation? And, in addition, I want the records (and this is a special point) from separate and distinct hedges or banks.

J. W. WILLIAMS.

57 Corinne Road, Tufnell Park, N.

Mr. Williams's "British Fossils."

IN my review of Mr. Williams's "British Fossils," published in NATURE of August 28 (p. 412), I notice a slip on my part in regard to eclogite. I should have said that whereas this rock is stated to consist of red garnets and hornblende, it is usually described as being composed of red garnets and one of the pyroxenes, such as omphacite or smaragdite, or both.

Since writing the review I have come to the conclusion that the twice repeated term "dermoid types" is intended for "demoid types"; a term used in the second edition of Phillips's "Manual of Geology." THE REVIEWER.

August 29.

A Remarkable Rainbow.

I HAVE just seen a very remarkable rainbow. It was plus 60° in height, and thin. The sunset was lurid, with a mock sun to the south of the real one. D. MACGILLIVRAY.

Oxford, August 25.

NOTES.

ON Sunday, August 17, M. Janssen ascended to the Grands Mulets, and next day he reached a hut called the Cabane des Bosses, which an Alpinist, M. Vallot, of Paris, has erected at a point about 400 metres below the summit of Mont Blanc. According to the Paris correspondent of the *Times*, the second day's journey was made in a sledge, drawn and pushed by twenty-two guides. Tuesday, Wednesday, and Thursday M. Janssen spent in a part of the hut which M. Vallot has fitted up as a scientific laboratory. On Friday, as the weather was very clear, M. Janssen had his sledge dragged up to the summit of the mountain to complete his observations. At the ridge of the

Bosses, which is almost vertical, and bordered on both sides by beds of snow ready to fall in avalanches at the slightest motion, the guides begged him to leave the sledge. He did so, but after taking five or six steps he fell exhausted on the snow and had to return to the sledge. He went back to the Grands Mulets the same day, and on the following Sunday he reached the Hôtel de Mont Blanc, and rejoined Mme. and Mdlle. Janssen, who had watched all his movements through a telescope. The results obtained by M. Janssen on this occasion confirm those to which he was led by his previous observations at the Grands Mulets.

THE medical profession loses much by the death of Dr. James Matthews Duncan, F.R.S. He died of heart disease at Baden-Baden, on Monday, September 1. He was born at Aberdeen in 1826.

WE regret to have to record the death of Prof. Carnelly. He died suddenly on August 27, at the age of 38. He had held the chair of chemistry at Firth College, and at the Dundee University College; and two years ago he was appointed Professor of Chemistry at Aberdeen.

ANOTHER death which we are sorry to have to record is that of Miss North, who died on Saturday, August 30, at her residence, Mount House, Alderley, Wotton-under-Edge, Gloucestershire, after a prolonged illness.

ORAZIO SILVESTRI, the distinguished chemist and vulcanologist, died at Catania on August 17. He was fifty-five years of age. In 1863 he was appointed to the professorship of chemistry at the University of Catania, whence he was transferred, in 1874, to a corresponding chair at the University of Turin. Afterwards he returned to Catania, where he became professor of mineralogy, geology, and vulcanology. Prof. Silvestri was an enthusiatic student of Mount Etna, and carried on many important investigations during the eruptions of 1865, 1869, 1879, 1883, and 1886. Through his efforts an astronomical and meteorological observatory has been constructed on Etna at a height of 3000 metres.

THE British Pharmaceutical Association held its twenty-seventh annual meeting in Leeds on Tuesday and Wednesday. The chair was occupied by Mr. Charles Umney. The attendance was unusually numerous.

THE Sanitary Institute had a most successful Congress at Brighton last week. Among the presidential addresses was one on "Geology in its relation to hygiene, as illustrated by the geology of Sussex," by Mr. W. Topley, F.R.S., President of the Section for Chemistry, Meteorology, and Geology. The discussions at the various meetings did much to foster the interest of the public in the laws of public health; and we should have been glad to devote more attention to the proceedings but for the pressure on our space due to the meeting of the British Association.

THIS week the International Congress of Agriculture and Forestry is holding a series of meetings at Vienna. There are delegates from Great Britain and many other countries. The proceedings began on Monday evening with a reception given by the organizing committee. On Tuesday the opening address was delivered by Count Christian Kinsky, President of the Diet of Lower Austria. The final sitting will be held on Saturday.

THE fourth annual series of vacation science courses at Edinburgh was brought to a close last Saturday with an excursion to Melrose and Abbotsford. These courses corresponded to the second part of the Oxford summer gathering, and were bly successful. A similar series is being organized for nter months, and will be specially adapted to "the edunal requirements of teachers."

ON August 27 and 28 earthquake shocks were felt along the Danube valley from Amstetten to Grein in Lower Austria. The seismic movement on August 28 lasted ten minutes, and was accompanied by a disturbance of the river, the water rising into long lines of waves similar to those caused by the paddle-wheel of a steamer.

THE Caucasus papers relate an interesting case of globular lightning which was witnessed by a party of geodesists on the summit of the Böhul Mountain, 12,000 feet above the sea. About 3 p.m., dense clouds of a dark violet colour began to rise from the gorges beneath. At 8 p.m., there was rain, which was soon followed by hail and lightning. An extremely bright violet ball, surrounded with rays which were, the party says, about two yards long, struck the top of the peak. A second and a third followed, and the whole summit of the peak was soon covered with an electric light which lasted no less than four hours. The party, with one exception, crawled down the slope of the peak to a better sheltered place, situated a few yards beneath. The one who remained was M. Tatosoff. He was considered dead, but proved to have been only injured by the first stroke of lightning, which had pierced his sheepskin coat and shirt, and burned the skin on his chest, sides, and back. At midnight the second camp was struck by globular lightning of the same character, and two persons slightly felt its effects.

A STUDY of five years' thunderstorms (1882–86) on the Hungarian plain has been recently made by M. Hegyfoky. We note the following points in his paper (communicated to the Hungarian Academy). The days of thunderstorm were those on which thunder was observed, and they formed 16·4 per cent. of all days from April to September. The air-pressure on those days sank about 2 mm. under the normal, morning and evening. The less the pressure, the greater the probability of thunderstorm. The temperature (estimated by the maximum thermometer) was higher than that of all days of the season indicated; and the moisture and cloudiness were similarly in excess. The wind blew about mid-day more softly, and in the evening more strongly than usual. It went round, as a rule, from the south-east by the south to the west and north-west. The clouds came oftener than usual from the south-east and south-west quadrants; so that the centre was generally north of the station. Nearly half of the season's rainfall was on days of thunderstorm. Hail fell on 11 days, on one of which there was no thunderstorm. There were most thunderstorms in June (59 out of 199). The June of 1886 had as many as 26. The commencement of a thunderstorm (first thunder) occurred most often from 2 to 5 p.m. Towards the end of the season the thunderstorms tend to come later in the day. When the pressure falls under the mean of the season (752·4 mm.), the thunderstorms last longer than when it is above the mean. The path was in most cases from south-west or west, and in most cases coincided with that of both lower and upper clouds, but in several cases only with that of the lower or upper. After the first thunder the meteorological elements are usually subject to great changes, most marked as the storm nears the zenith: rain falls, wind rises, and alters quickly in direction, temperature and vapour-pressure fall, relative humidity, cloud, and pressure increase. As the storm withdraws there is a return to the normal. Various other points are considered. The author accepts Sohncke's theory—that the electricity of thunderstorms is due to friction of water-drops on ice.

THE Meteorological Council have just published a series of observations made at Sanchez (Samaná Bay), St. Domingo, in the years 1886–88. They were made chiefly by the late Dr. W. Reid, Medical Officer of the Samaná and Santiago Railway Company. The Council, recognizing the value of the observations, which

were taken with much care, and for a locality for which they are very scarce, determined to publish them in detail. The monthly means and summaries have been calculated in the Meteorological Office and added in a convenient form at the end of the volume. From these it is seen that the maximum shade temperature was 96°·5 in September 1887, and the minimum 58°·5 in March 1888. The rainfall varied considerably in the different years—as much as 26 inches. The greatest daily fall was 6 inches in April. The sunshine recorded in 1888 amounted to an average of 6·7 hours daily. Dr. Reid remarks, with regard to the wind, that in about 19 days out of 20 there is a light breeze in the west at 6h. a.m., which continues till about 8h. a.m., then a short calm, then a light breeze from about south, which veers round to east or east-south-east by 10 a.m., and there continues till about 4 p.m., when it remains calm till next morning. Only three gales are recorded during the three years, and these all occurred in 1886.

THE *Pall Mall Gazette* has issued in its "Extra" series a charming story of a dog. It is called "Teufel the Terrier: the Life and Adventures of an Artist's Dog," and is "told by J. Yates Carrington, and edited by Charing Cross." The tale is admirably illustrated, and will give much pleasure to all who study the ways of dogs, and appreciate their intelligence and sense of fun.

PART 23 of Cassell's "New Popular Educator" has been published. Besides the woodcuts in the text, there is a coloured plate illustrating electric discharges in rarefied gases.

MESSRS. GEORGE L. ENGLISH AND CO., of Philadelphia and New York, have published the fifteenth edition of their catalogue of the minerals which they have for sale. There has been in America, they say, a "very great increase in the demand for mineral specimens."

THE proposed creation of Universities in France will soon give rise to much animated discussion in the French Senate. Meanwhile, the Ministry of Public Instruction has prepared a return showing the number of students who at present attend the different French faculties. The total is 16,587, of whom 15,316 are Frenchman and 1271 foreigners, as against only 9863 fifteen years ago. Of this total 5843 students attend the faculty of medicine, 4570 that of law, 1834 that of literature, 1590 that of pharmacy, 1276 that of science, and 101 that of Protestant theology. Rather more than half of these (8653) are students of the different Paris faculties, and of the 1271 foreign students 1078 are in Paris. There are 989 Europeans (313 Russians, 159 Roumanians, and 121 Turks), 201 Americans (of whom 173 come from the United States), 68 Africans (of whom 51 are Egyptians), 12 Asiatics, and 1 Australian. The great majority of these foreigners are studying medicine; 907 belong to that faculty, while 240 are studying law, 58 science, 39 pharmacy, 24 literature, and 3 Protestant theology.

THE *Japan Weekly Mail* in a recent issue notices the publication of a kind of Japanese folk-lore journal, called the *Fuzoku Gwahōo*, the object of which is to collect and record important and curious Japanese national customs. Japanese customs, old and new, are classified by the new journal under seven heads—namely, customs that concern (1) human beings, (2) animals and plants, (3) dress and ornaments, (4) food and beverages, (5) buildings, (6) furniture and coins, (7) miscellaneous. For the illustrations resort is had to old pictures. Every number contains an essay on some interesting custom, with allusions to authorities on the subjects treated.

THE Government of India, it is reported, has decided to discontinue the annual grant hitherto devoted to search for, and purchase of, rare Sanskrit manuscripts, but the decision will not take effect until 1892. A regular staff of native searchers have been employed during the past ten years, and these have visited most of the large temples throughout India, examining and cataloguing the vast collections of works hoarded up there. The private libraries of several native gentlemen have been likewise carefully sifted, and their contents recorded. Of the manuscripts thus examined, no fewer than 2400 have been purchased by the Government, and rendered accessible to the public at Bombay and Calcutta. The most valuable "finds" have included numerous old Jain manuscripts, now being submitted to the scrutiny of competent scholars in Bombay. Although the search and purchase grants are to cease, the Indian Government has agreed to continue the allowance of Rs. 9000 per annum for the publication of texts and translations of the Sanskrit and Persian works discovered.

THE additions to the Zoological Society's Gardens during the past week include a Squirrel Monkey (*Chrysothrix sciurea* ♀) from Guiana, presented by Mrs. Osgood; two Chinese Alligators (*Alligator sinensis*) from China, presented by Mr. D. C. Jansen; a Great-billed Touracou (*Corythaix macrorhyncha*) from West Africa, a Wonga-wonga Pigeon (*Leucosarcia picta*) from Australia, a Madagascar Love Bird (*Agapornis cana*) from Madagascar, purchased.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on September 4 = 20h. 55m. 52s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.

(7) V Cygni	Var.	Red.	20 37 46	+47 45

Remarks.

(1) The G.C. description of this nebula is: "Considerably bright; large; elongated in the direction 45° or thereabouts; barely resolvable." The spectrum appears to have been observed only by Dr. Huggins, who recorded:—"One bright line only was distinctly seen, of apparently the same refrangibility as the brightest of the nitrogen lines. This bright line appeared by glimpses to be double. Possibly this appearance was due to the presence near it of a second line. The faintness of the light did not permit the slit to be made sufficiently narrow for the determination of this point." This is an observation well worth repeating, as it may possibly throw some light on the origin of the chief nebula line. The magnesium fluting near λ 500 has been suggested, on various grounds, as the origin of the chief line, and this consists of a rhythmical series of flutings with well-defined edges towards the red end of the spectrum. It may be that the second faint line seen by Dr. Huggins was the second maximum of the compound fluting, but unfortunately he does not state whether it was more or less refrangible than the brighter line.

(2) It appears to be generally agreed that this is one of the finest specimens of planetary nebulæ in the heavens. Lassell saw it as an elliptic ring with a star in the centre. Dr. Huggins and Lieutenant Herschel each recorded three bright, sharp, and distinct lines in its spectrum, and Prof. Winlock suspected a fourth. The spectrum of this nebula might perhaps be advantageously observed in connection with that of the previous nebula. As the temperature of nebulæ indicating hydrogen is probably lower than that of nebulæ in which the hydrogen lines are absent, there is reasonable ground for supposing that the fluted appearance of the chief line (assuming it to be due to

magnesium) will be most obvious when the hydrogen lines are not seen. A comparison of the two spectra with the same instruments under similar conditions will therefore be valuable.

(3) This comparatively bright star of Group II. has not yet been observed in sufficient detail, Dunér simply stating that the bands 2–8 are wide and dark. For purposes of classification it is also necessary to know whether the bands in the blue or those in the red are most intense.

(4 and 5) These are stars of the solar type and of Group IV. respectively (Konkoly). The usual observations are required in each case.

(6) Dunér describes the spectrum of this star as one of Group VI., consisting of three zones, of which the blue is also pretty bright. The principal bands are very dark, and the secondary bands 4 and 5 (λ 589 and 576) were also occasionally seen. The brightness of the blue zone varies very considerably in stars of this group, and, moreover, does not depend upon the magnitude of the star. It probably therefore depends upon temperature. The associated phenomena are well worth investigation.

(4) This interesting variable will reach a maximum about September 6. The observations of the magnitude at maximum are a little discordant, but there can be no doubt that it changes considerably, the extremes being 6·8 and 9·5, whilst the minimum is a prolonged one of about magnitude 13. The spectrum is one of Group VI., showing very little blue light. Continuous spectroscopic observations will be very valuable in connection with Mr. Lockyer's theory of the cause of variability in stars of this group.

A. FOWLER.

VARIABLE STARS NEAR THE CLUSTER 5 M.—At the June meeting of the Royal Astronomical Society, Mr. A. A. Common, F.R.S., exhibited some photographs of the cluster 5 Messier, taken with his 5-foot telescope at Ealing. Four photographs had been taken on April 22, May 9, May 15, and June 9, with exposures of 25, 45, 66, and 45 minutes respectively. The plate taken on May 15—that is, the one with the longest exposure—contains five stars not shown on those taken before and after that date. The presence of these five stars was not due to longer exposures because they were all brighter than the 10th magnitude, whereas stars of at least the 12th magnitude were seen on all the plates. A great difference was also observed in the apparent magnitudes of many of the stars near the cluster.

Prof. E. C. Pickering notes (*Astronomische Nachrichten*, No. 2986) that an examination of the photographs of this region taken at Harvard College Observatory proves beyond doubt that the star about 9″ or 10″ south preceding the cluster varies between 9·76 and 11·6 magnitude, and that the south component of the wide pair just following the cluster varies between 9·3 and 12·2 magnitude.

NEW ASTEROIDS.—A new minor planet (295), of the 13th magnitude, was discovered by Dr. Palisa, at Vienna, on August 17; and another, (296), by Mr. Charlois, at Nice, on August 19. The latter was found near the position of Hera, (103), but because of the difference in magnitude it is thought to be new.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 25.—On a jawbone of a Greenland seal, found by M. Michel Hardy in the grotto of Raymonden.—Observations of the Denning (July 23, 1890) Comet, made at the Paris Observatory, by M. G. Bigourdan.—Observations of the new planet Palisa (Vienna, August 17, 1890), made at the Paris Observatory, by Mdlle. D. Klumpke.—Elements and ephemerides of the planet (294), discovered at the Nice Observatory, July 15, 1890, by M. Charlois.—On two forms of electrical gyroscopes, one serving to show the movement of the earth, and the other for the rectification of the marine compass, by M. G. Trouvé. The two instruments are similarly constructed, but the latter is heavier, and so hung as to be free from the various causes of disturbance always present on board. It is able to correct the compass with certainty, since its axis of rotation remains fixed in space, however long it is necessary to prolong the observation.—On the respiration of the grasshopper, by M. Ch. Contejean. The abdomen is chiefly concerned with the respiratory movements. Stimulation of the nervous system by applying induced electric currents causes an obvious acceleration in the breathing.—New researches on the production of light by animals and vegetables, by M. Raphael Dubois. The author concludes that the production of light in animal organisms is due to the transformation of the colloidal protoplasmic granulations into crystalloidal granulations, under the influence of a respiratory phenomenon.—On the presence of the carboniferous formation in Brittany, by M. P. Lebesconte. This paper contains a list of the fossils obtained from some newly-discovered fossil-bearing strata in the carboniferous limestones at L'Ille-et-Vilaine in Quenon.—On the storm of August 18, 1890, at Dreux, by M. Léon T. de Bort. In its local and destructive character this storm showed many analogies with the tornadoes of the United States.—Notes were also submitted by M. Chapel, on the coincidence of atmospheric disturbances with the meeting with the Perseids; by M. van Heyden, on the height of the atmosphere; and by M. E. Mathieu-Plessy, on a new base obtained by heating ammonium nitrate, possibly nitramide, $NO_2 . NH_2$.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Principia; or, the Three Octaves of Creation: Rev. A. Kennion (E. Stock).—Transactions and Proceedings of the New Zealand Institute, 1889, vol. xxii.: Sir J. Hector (Trübner).—Paul Nugent, Materialist, 2 vols., 3rd edition: H. F. Hetherington and Rev. H. D. Burton (Griffith and Farran).—Annual Report of the Department of Mines, New South Wales, for the year 1889 (Sydney).—Inorganic Chemistry: Wm. Jago (Longmans).—Wild Flowers of North Wales Coast; R. PRINCIPLES OF ORGANIC CHEMISTRY.

Principles of General Organic Chemistry. By Prof. E. Hjelt, Helsingfors. Translated from the Author's German Edition of the original work by J. Bishop Tingle, Ph.D. (London: Longmans, Green, and Co., 1890.)

THIS work is an English translation of the German edition of a book which originally appeared in Swedish, and its object is stated to be "to give in a short and clear form the most important points of general and theoretical organic chemistry." Paraphrasing a statement recently put forward by a well-known reviewer in these columns, we certainly doubt the propriety of translating German books of this kind into English, regarding the ignorance of German by a chemist as inexcusable, if not criminal: in our opinion, indeed, permission to study the science of chemistry should be contingent on proof being given of a competent knowledge of this language. But our objection does not rest alone on this basis: we should not even have recommended the translation of the work from Swedish, as we hold that its study must have a thoroughly demoralizing effect. It is impossible "to give the most important points of general and theoretical organic chemistry," in accordance with the plan adopted by the author, within so narrow a compass; and such a book can only serve the purposes of the crammer. The uselessness of attempting to construct a cottage from plans prepared for a mansion needs no proof, but it is just such an attempt that is made in the book under notice.

The book is divided into three parts. According to the translator, in Part I. the composition, constitution, and classification of organic compounds are discussed and explained as clearly and concisely as possible. Part II. is devoted to illustrating the connection between the constitution of organic compounds and their chief physical properties. Part III. deals with the chemical behaviour of organic compounds. In illustration of the treatment accorded to the various sections, it may be mentioned, however, that the whole subject of "Geometrical Isomerism," one of the most difficult of modern chemical problems, is dismissed in five pages; that optical properties occupy but five and a half; and that only three and a half are devoted to the discussion of specific gravity and specific volume in their relation to constitution.

Some among us contend that the study of chemical science affords logical training of a very high order, but certainly this would not be the opinion of any intelligent person unacquainted with the subject who chanced to read this book. Thus, what can be the value of such wretched mental pabulum as that supplied on pp. 42-43, where, after the briefest possible reference to the van t' Hoff-Le Bel hypothesis, we read, "Two doubly linked carbon atoms would be represented by a figure consisting of two tetrahedra with one edge in common. Two arrangements are possible of substances of the type $Cab = Cab$. Fumaric and maleic acids are examples of such compounds"? Then follow the two conventional double tetrahedron figures, and a few lines further comes the dogmatic assertion, "It can be proved that fumaric acid is constituted like Fig. 2, and maleic acid like Fig. 1. It is not possible here to give a systematic account of the principles upon which the discovery of geometrical isomerism is based." Fancy the effect of studying, let us say, Euclid on such principles, and the kindly reception the lad would meet with who told his master in class that "*it can be proved* that any two sides of a triangle are greater than the third," and whose knowledge went no further; yet this is about the position which a reader of this book would be placed in after perusing its fragmentary sentences. If the student be exceptionally intelligent, and be not satisfied with dogmatic assertions, what must, moreover, be his opinion of his teacher when later on he directs his attention to current literature, and finds that the constitution of fumaric and maleic acids is one of the questions which is being hotly contested among chemists; that it is not proved that either acid has the constitution represented by the figures given; that, in fact, it is pure assumption that such is the case; and that the determination of the constitution of these and similar acids is a problem of peculiar difficulty?

The translator tells us that "No pains have been spared in order to bring the work into harmony with the latest researches, though of course, from the very nature of the case, all controversial matter has been excluded." The first part of the sentence is distinctly misleading, and it is difficult to understand the meaning of the latter. Our methods of determining constitution are admittedly in so many cases imperfect and but roughly approximate; so much depends on individual judgment, and the point of view from which the interpretation is given; that, in discussing constitution and the relation of physical properties to structure, "controversy" cannot be excluded. The advancing student has the right to demand a statement of the arguments for and against, and to nourish him on dogma is to do him a grievous injury: his object being to learn to play the game himself later on, he desires to obtain an insight into its rules and moves, and his only chance of learning methods is to become acquainted with the methods and arguments of previous workers. An illustration is afforded by chapter xi., on heat of combustion and heat of formation, which extends to the inordinate length of two pages and a half. In this chapter reference is made to Thomsen's calculations of the thermal values of the different kinds of bonds between carbon atoms, and his conclusions are put forward in such a manner as to lead the student to suppose that they are based on cogent arguments. The author's preface being dated Helsingfors, February 1887, it is excusable that he should have been impressed by the weight of Thomsen's authority; but it is inexcusable that the translator, three years later, should overlook the criticisms that have been passed on Thomsen's work, and should fail to point out that the conclusions which this chemist based on his thermal studies of carbon compounds are frequently in absolute conflict with those deduced from the study of chemical behaviour. The survival at this date of the strange conclusion that in acetylenic compounds the carbon atoms are held together by less than no affinity clearly shows that common-sense after all is an uncommon sense. The concluding paragraph of chapter xi. is

one which it is perhaps undesirable to pass without remark :—

"All researches prove that unsaturated compounds possess a greater heat of combustion than saturated ones; their heats of formation are therefore less and their energy greater than that of compounds containing carbon atoms linked only by single bonds. The thermal behaviour of unsaturated compounds also shows that the so-called *double bond is a weaker, not a stronger, form of atomic attraction than the simple bond.*"

The first of these sentences is a mere statement of fact; the second is an unwarrantable and illogical deduction from the facts, and yet the fallacy which it embodies is very generally overlooked. Chemists are persuaded that the ethylenic form of linkage is not the equivalent of *two* paraffinic linkages, but is considerably weaker; beyond this, however, all is surmise. It is not determined whether or no the carbon atoms in ethylenic compounds are united by more than a single affinity; and as we have no means at present of calculating the thermal equivalent of even a paraffinic linkage, thermal behaviour cannot enable us to judge which is the stronger form of atomic attraction—the paraffinic or the ethylenic. The greater stability of saturated as compared with unsaturated compounds would appear to be due to the greater readiness with which the latter are acted on. To defeat an enemy it is necessary to approach within striking distance; and so it is in affairs chemical. The vulnerable points in saturated compounds are few or limited in extent, but in the case of the unsaturated it is easy for the attacking party—the chemical agent—to effect a lodgment.

Our criticisms thus far have had reference chiefly to Parts I. and II.; but of Part III., which is the more important section of the book and the more novel in plan, we cannot speak in terms much less unfavourable. We can only say: Defend us from the student whose knowledge of the general behaviour of organic compounds has been derived from such a course of study. We wish, in the interests of English chemical students, that the book had remained untranslated.

H. E. A.

THE THEORY OF INTEREST.

Capital and Interest: a Critical History of Economic Theory. By Prof. Eugen von Böhm-Bawerk. Translated by William Smart, M.A. (London: Macmillan and Co., 1890.)

PROF. SMART shares with Mr. James Bonar the honour of introducing to the English public a leader of the important Austrian school of economists. Mr. Bonar, in the *Quarterly Journal of Economics*, transfuses into his own happy style the spirit of Prof. Böhm-Bawerk's theory of value. Prof. Smart translates the same writer's theory of interest, which, to be fully appreciated, should be read in connection with the earlier work. The translation is enhanced by an analysis and a preface, in which the author's theory is, so to speak, "brought down to earth," and adapted, by examples taken from the highway and the market-place, to the comprehension of the wayfaring man. Referring to his own labours, Mr. Smart makes a suggestion which deserves attention :—

"The time I have given to this work may excuse my suggesting that a valuable service might be rendered to the science, and a valuable training in economics given, if clubs were organized, under qualified professors, to translate, adapt, and publish works which are now indispensable to the economic student."

Mr. Smart should be one of these professors; for he has proved himself to be eminently qualified, not only to translate, but to adapt an important work.

One quality of this work, about the excellence of which there can be no question, is the learning with which it abounds. The Austrian economists rival their German neighbours of the exclusively "historical" school in laboriousness of research. He must be a ripe scholar to whom many even of the names, as well as matters, in our author's review of theorists and theories are not new. We shall not expose our own ignorance by mentioning the writers of whom we had never heard before. As an instance of one whose name was not unknown, but whose position in economical history was not sufficiently recognized, may be noticed Salmasius. The average English reader is aware that Salmasius was underrated by Milton and his biographer, Dr. Johnson. But it requires Prof. Böhm-Bawerk's acquaintance with economic literature to realize how much Salmasius contributed to the explosion of the old prejudices against interest. Not only does his doctrine

"indicate an advance, but it long indicates the high-water mark of the advance. . . . There was no essential advance on Salmatius (in respect of the theory of interest) till the time of Smith and Turgot."

J. B. Say, if we remember rightly, has observed that there is not much use in studying the theories of the earlier economists, as they were mostly wrong. Prof. Böhm-Bawerk evidently does not accept this somewhat Philistine conclusion. But we suspect that he does not deny the premiss. For it appears to be the motive of this "Critical History of Economic Theory" to prove that all preceding economists have gone astray, and fallen short of the glory which we fully concede appertains in a special degree to Prof. Böhm-Bawerk as the formulator of the true theory of interest. Now we cannot agree to the negative proposition here implied. Our approbation of Prof. Böhm-Bawerk does not rest upon the censure of his predecessors. Of course it must be admitted that on the theory of interest, as on other economical subjects, a great deal of nonsense has been talked. But—hindered perhaps by the proverbial difficulty of unlearning the lessons of youth—we can hardly believe that the leaders of economic thought, that Ricardo and Senior and J. S. Mill, deserve to be involved in such a sweeping condemnation.

In expressing this doubt we shall shelter ourselves behind the authority of one to whom most readers conversant with economic science will be disposed to defer. In one of the scrupulously weighed notes attached to the epoch-making work which Prof. Alfred Marshall has just published, he thus refers to Prof. Böhm-Bawerk :—

"The question may be raised whether he has not somewhat exaggerated the difference between his own position and that of his predecessors; whether the sharp contrasts which he finds between the doctrines of successive schools really existed, and whether those doctrines

were generally as fragmentary and one-sided as he thinks."

Without attempting to add to words so weighty, we shall follow the excellent example of him who had to speak after Mr. Burke, and shall simply "say ditto" to Prof. Marshall.

It is not be supposed that our remarks are calculated to disparage the truth and importance of Prof. Böhm-Bawerk's own theory of interest. It would argue a very slight acquaintance with economical literature to suppose that the worth of an author's own work is to be measured by the worth of his criticisms upon the work of others. Prof. Böhm-Bawerk is not the less right because those from whom he differs are not wrong. We are not precluded from expressing unqualified admiration of the *positive theory* which forms the sequel to this too "critical" history. F. Y. E.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Soaring of Birds.

IN NATURE of August 21 (p. 397), a new solution has been offered of the problem of the soaring of birds, which will hardly be accepted as satisfactory; for it is based on the radical misconception that the absolute velocity with which a bird soars, or flies, partly with the air, and partly through the air, can be converted, wholly or in part, into a motion through the air, at a swifter rate than before. This is only possible when the bird passes from one current into another, or the current itself is changed in rate or direction. It is strange that anyone should fail to see that when a body of air is moving uniformly over the land or sea, it can no more sustain a bird flying or gliding within it than if it were motionless.

Referring to your correspondent's first diagram, "It is evident," he says, "that the velocity of the bird at the point *c*, if the initial velocity of the bird and the velocity of the wind are properly adapted" (whatever that may mean) "can be greater than at *a*. He appears to think that the length of the line *a c* is some measure of the velocity; whereas, in fact, this velocity will be the same, or rather greater, indefinitely near to *a* than it is at *c*; the velocity of the bird through the air being then at its maximum, and that of the wind uniform. Nothing is gained by the length of *c a*. A movement in the direction *c d* might be at least as advantageously made close to *a* as further along the line.

It is hardly worth while to press any other objection to the explanation offered. But it may be noted that if the diagrams given are intended to represent the actual facts the soaring bird is being rapidly carried to leeward, which is a misrepresentation. Let me offer what I believe to be an apt illustration. While a billiard ball is rolling across a table, its direction being again and again changed by its rebounds from the cushions, the table is moved forward through space at the rate of about a thousand miles a minute. This movement ought, according to your correspondent, to accelerate or retard the motion of the ball across the table, or at least ought to do so if the two movements were "properly adapted."

REGINALD COURTENAY.

Tean Vicarage, Stoke-on-Trent, September 1.

[P.S.—In NATURE for September 4 (p. 457), just received, are remarks on the soaring of birds, by two of your correspondents, which seem to me to be perfectly just; only I would add that the upward currents of which soaring birds avail themselves are commonly due to obstacles to the uniform motion of the wind. Also, that a soaring bird, if turning abruptly, will in general not merely uplift, but strike once, with the outer wing.]

The Affinities of *Heliopora cærulea.*

OWING to absence from Dublin I have but just seen the correspondence on the affinities of *Heliopora cærulea* in two recent numbers of NATURE (pp. 349, 370). Dr. S. J. Hickson has undoubtedly given the true explanation of Mr. Saville Kent's "curious mistake." Knowing that the polyps of this Alcyonarian had never before been observed in expanded condition, I took every opportunity when in Torres Straits of examining living specimens *in situ.* Only on one occasion was I rewarded, and then I distinctly saw the small extruded polyps with their eight flat fringed tentacles; they were nearly colourless, but had a whitish tinge, in fact, they precisely resembled the polyps of the common *Alcyonium digitatum.* I was unable to sketch them at the time, as my bodily position was unfavourable, and the tide was rising. In no case did the polyps exhibit any sign of vitality when kept in a vessel of water in my laboratory. The only published drawing (so far as I remember) purporting to be the polyp of this form is that given by Quoy and Gaimard, but whatever it may be, it represents neither the polyp itself nor the annelid described by Mr. Saville Kent.

ALFRED B. HADDON.

Royal College of Science, Dublin.

Occurrence of a Crocodile on Cocos Islands.

WITH reference to Mr. Ridley's account of the occurrence of a crocodile on the Cocos Islands, I was quartered in Barbados in the beginning of 1885, when a very fine alligator, over 15 feet in length, was washed on shore. As it was on the point of crawling up the beach it was noticed by a sergeant of engineers and some sappers who shot it, and afterwards exhibited it in the town.

The nearest river the alligator could have come from was the Orinoco, a distance of 300 miles.

This is improbable, as the set of the ocean currents would have sent the alligator much to the west of Barbados if it had come from the Orinoco. It is much more probable the alligator came from the mouth of the Amazon or from the Essequibo, many hundred miles further to the east.

Dr. Mitchell, of Trinidad, told me he had seen an alligator on a small log attacked by sharks in the Gulf of Paria.

A. L. CALDWELL.

A.S. Corps, Chatham, September 6.

THE BRITISH ASSOCIATION.

LEEDS, *Wednesday Morning.*

THE Leeds meeting has been small and quiet, the attendance only numbering over 1700. Happily the weather has been excellent, and brilliant sunshine has cast a glow over the ugliness of the place, and rendered the excursions to the Aire and the Wharfe valleys delightful. The usual social accompaniments of British Association meetings have not been so plentiful as at former meetings, but every one seems satisfied with the hospitality displayed.

In the proceedings of the meeting there have been one or two matters of excitement and some marked successes. Sir Frederick Abel considerately cut down an address which was more suited for the study than the platform. It is universally admitted that no more successful lectures have ever been delivered at an Association meeting than those of Mr. Poulton on Friday, on "Mimicry," and Prof. Boys on Monday, on "Quartz Fibres." The large audiences were really entranced.

It can hardly be said that any paper of high and wide scientific importance has been read this year in any of the Sections. There have, however, been several most important discussions on the reorganization of some of the Sections, which attracted much attention, and several changes are to be made.

Next year's meeting of the Association will take place at Cardiff, when Dr. Huggins will preside. The 1892 meeting will be held at Edinburgh, and the 1893 at Nottingham.

The following is the list of grants to be submitted to the meeting of the General Committee to-day:—

A.—*Mathematics and Physics.*

	£
Seismological Phenomena of Japan	10
Electrical Standards	100
Meteorological Observations on Ben Nevis	50
Electrolysis	5
Photographs of Meteorological Phenomena	5
Discharge of Electricity from Points	10
Ultra-Violet Rays of Solar Spectrum	50
Seasonal Variations of Temperature	20

B.—*Chemistry.*

Analysis of Iron and Steel	10
Isomeric Naphthalene Derivatives	25
Formation of Haloid Salts	25
Action of Light upon Dyes	20

C.—*Geology.*

Erratic Blocks	10
Fossil Phyllopoda	10
The Geological Record	100
Photographs of Geological Interest	10
Lias Beds in Northamptonshire	20
Registration of Type Specimens of British Fossils	10
Volcanic Phenomena of Vesuvius	10
Underground Waters	5
Investigation of Elbolton Cave	25

D.—*Biology.*

Marine Biological Association at Plymouth	30
Botanical Station at Peradeniya	50
Improving Deep-sea Tow-net	40
Disappearance of Native Plants	5
Zoology of the Sandwich Islands	100
Zoology and Botany of the West India Islands	100

E.—*Geography.*

Normal Tribes of Asia Minor and Northern Persia	30

G.—*Mechanical Science.*

Action of Waves and Currents in Estuaries	150

H.—*Anthropology.*

New Edition of "Anthropological Notes and Queries"	50
Anthropometric Laboratory	10
North-western Tribes of Canada	200
Habits of Natives of India	10
Corresponding Societies	25
	£1330

SECTION A.

MATHEMATICS AND PHYSICS.

Opening Address by J. W. L. Glaisher, Sc.D., F.R.S., President of the Section.

No one who is called upon to preside over this Section can fail to be struck by the range of subjects comprehended within its scope. The field assigned to us extends from the most exact of all knowledge, the sciences of number, quantity, and position, to branches of inquiry in which the progress has been so slight that they still consist of little more than collections of observed facts. This breadth of area has obvious disadvantages, but it is not without some compensating advantages. In these days, when science is so much subdivided, it is well that students of subjects even so diverse as those with which we have to deal should occasionally meet on common ground, and have the opportunity of learning from each other's lips the kind of work in which they are engaged. Wide as is our range, we should remember also how closely knit together in various ways are the more important of our subjects; and in the case of mathematics, astronomy, and physics, besides their actual and historical alliance, a mathematician may be permitted to feel that a special bond of union is created by the mathematical processes and language which are essential for their investigation and expression.

It is, I am afraid, unfortunate for my audience, that my own subject should be at one extreme, not only of those dealt with by our Section, but even of the still greater range covered by the Association. I will endeavour, however, in my remarks to confine myself to a few general considerations relating to pure mathematics, which I hope will not be considered out of place on this occasion.

By pure mathematics I do not mean the ordinary processes of algebra, differential and integral calculus, &c., which every worker in the so-called mathematical sciences should have at his command. I refer to the abstract sciences which do not rest upon experiment in the ordinary sense of the term, their fundamental principles being derived from observations so simple as to be more or less axiomatic. To this class belong the theories of magnitude and position, the former including all that relates to quantity, whether discrete or continuous, and the latter including all branches of geometry. The science of continuous magnitude is alone a vast region, containing many beautiful and extensive mathematical theories. Among the more important of these may be mentioned the theories of double and of multiple periodicity, the treatment of functions of complex variables, the transformation of algebraical expressions (modern algebra), and the higher treatment of algebraical and differential equations as distinguished from their mere solution. It is this kind of scientific exploration which fascinates and rewards the pure mathematician, and upon which his best work is most profitably spent. I do not wish to under-estimate the importance of such a subject as finite differences, in which a number of distinct problems are treated with more or less success by interesting methods specially adapted to their solution. Nor would I willingly undervalue the interest of those branches of mathematics which we owe to the mathematical necessities of physical inquiry. But it always appears to me that there is a certain perfection, and also a certain luxuriance and exuberance in the pure sciences which have resulted from the unaided, and I might almost say inspired genius of the greatest mathematicians which is conspicuously absent from most of the investigations which have had their origin in the attempt to forge the weapons required for research in the less abstract sciences. To illustrate my meaning, I may take as an example of a subject of the latter class the theory of Bessel's functions. The object of mathematicians in this case has been to investigate the properties of functions which have already presented themselves in astronomy and physics. Formulæ for their calculation by means of series, continued fractions, definite integrals, &c., have been obtained in profusion, numerous theorems of various kinds and applicable to different purposes have been discovered, extensions and developments have been made in all directions, and, finally, the large body of interesting analysis thus accumulated has been classified and systematized. But, valuable and suggestive as are many of the results and processes, such a collection of facts and investigations is necessarily fragmentary. We do not find the easy flow or homogeneity of form which is characteristic of a mathematical theory properly so called. In such a theory as, for example, the theory of double periodicity (elliptic functions), the subject develops itself naturally as it proceeds; one group of results leads spontaneously to another; new and unexpected prospects open of themselves; ideas the most novel and striking, which penetrate the mind with a charm of their own, spring directly out of the subject itself. We are surprised by the wonderful connections with other subjects which unexpectedly start into existence, and by the widely different methods of arriving at the same truths; in fact, as our knowledge progresses, we continually find that results which seemed to lie far away in the interior of the subject—so remote and concealed that, at first sight, we might think that no other path except the one actually pursued could have reached them—are actually close to its edge when approached from another side, or viewed from another stand-point. We notice, too, that any great theory gives rise to its own special analysis or algebra, frequently connecting together into one whole what were hitherto merely isolated and apparently independent analytical results, and affording a reason for their existence, and also—what is often even more interesting—a reason for the non-occurrence of others, which analogy might have led us to expect. I do not

pretend that there are not many branches of mathematics which partake of both these characters, nor do I suppose that the description I have given of a mathematical theory is at all peculiar to pure mathematics. Much of it is common to all scientific research in a fruitful field, though, possibly, we may not find elsewhere such profusion of ideas or perfection of form.

I have been tempted to speak at such length on the objects and aims of the mathematician by the feeling that they are not infrequently misunderstood by the workers in the less abstract sciences. I do not think that mathematical formulæ or processes, merely as such, are much more interesting to the pure than to the applied mathematician. The one studies number, quantity, and position, the other deals with matter and motion; and in both cases the investigations are carried on by means of the same symbolic language.

The order in which the subjects which form an ordinary mathematical course are presented to the student is regulated by the fact that portions of the elements of the pure sciences are required for the explanation and development of any exact science; for example, a knowledge of the elements of trigonometry, analytical geometry, and differential and integral calculus, must necessarily precede any adequate treatment of mechanics, light, or electricity. The majority of students, after mastering a sufficient amount of pure mathematics to enable them to pass on to the physical subjects, continue to devote their attention to the latter, and never know more of the nature of the pure sciences than they can derive from the processes and methods which they learned at the very outset of their mathematical studies. This is necessarily the case with many of the wranglers, as the first part of the Mathematical Tripos includes no true mathematical theory. Most of the mathematical text-books in use at Cambridge are so admirably adapted to the purposes for which they are intended that it seems ungracious to make an adverse criticism of a general kind. But I cannot help feeling regret that their writers have had so much in view the immediate application of the principles of the pure subjects to the treatment of physical problems. In the case of the differential and integral calculus, for example, there seems an increasing tendency to introduce into the book-work and examples propositions which really belong to the physical subjects. This is an important tribute to the growth and influence of physical mathematics in this country, and a zealous physicist might even consider it satisfactory that the student should not be required to encumber himself with knowledge which was not directly applicable to the theory of matter. But from the mathematician's point of view it is unfortunate, for, while shortening by very little the path of the student, it cannot fail to give an incomplete, if not erroneous, idea of the relations of the pure to the applied sciences. How can he help feeling that the former are merely ancillary to the latter when he finds that the mathematical problems which arise naturally in physical investigations have been already dealt with out of their place in the treatises which should have been devoted solely to the sciences of quantity and position?

Perhaps few persons who have not had the matter forced upon their attention fully realize how fragmentary and unsatisfactory is the treatment of even those fundamental subjects in pure mathematics which form the groundwork of any course of mathematical study. Algebra is necessarily the first subject set before the student; it has therefore to be adapted to the beginner, who at that time is only learning the first elements of the language of analysis. It is customary to regard trigonometry as primarily concerned with the solution of triangles; the geometrical definitions of the sine and cosine are therefore adopted, and after the application of the formulæ to practical measurement and calculation a new departure is made with De Moivre's theorem. The elementary portions of the theory of equations, and the differential and integral calculus and differential equations, are valuable collections of miscellaneous principles, processes, and theorems, useful either as results or as instruments of research, but possessing no great interest of their own. Analytical geometry fares the best, for it includes one small subject—curves of the second order—which is treated scientifically and with thoroughness. It is true, however, that the course of reading just mentioned includes one theory which, though itself an imperfect one, receives a tolerably complete development—I mean the theory of singly periodic functions; but it is dispersed in such small fragments among the various subjects that it does not naturally present itself to the mind as a whole. If we could commence this theory by considering analytically the forms and necessary properties of functions of one period (thus obtaining their definitions as series and products), and could then proceed to a detailed discussion of the functions so defined—including their derivatives, the integrals involving them, the representation of functions by their means in series (Fourier's theorem), &c.—we should obtain a connected system of results relating to a definite branch of knowledge which would give a good idea of the orderly development of a mathematical theory; but the fact that the student at the time of his introduction to sines and cosines is supposed to be ignorant of all but the most elementary algebra, places great difficulties in the way of any such systematic treatment of the subject.

Passing now to the consideration of pure mathematics itself, that is to say, of the abstract sciences, which can only be conquered and explored by mathematical methods, it is difficult not to feel somewhat appalled by the enormous development they have received in the last fifty years. The mass of investigation, as measured by pages in Transactions and Journals, which is annually added to the literature of the subject, is so great that it is fast becoming bewildering from its mere magnitude, and the extraordinary extent to which many special lines of study have been carried. To those who believe, if any such there are, that mathematics exists for the sake of its applications to the concrete sciences, it must indeed seem that it has long since run wild, and expanded itself into a thousand useless extravagances. Even the mathematician must sometimes ask himself the question—not infrequently put to him by his friends—"To what is it all tending? What will be the result of it all? Will there be any end?" The last question is readily answered. There certainly can be no end; so wide and so various are the subjects of investigation, so interesting and fascinating the results, so wonderful the fields of research laid open at each succeeding advance—no matter in what direction—that we may be sure that, while the love of learning and knowledge continue to exist in the human mind, there can be no relaxation of our efforts to penetrate still further into the mysterious worlds of abstract truth which lie so temptingly spread before us. The more that is accomplished, the more we see remaining to be done. Every real advance, every great discovery, suggests new fields of inquiry, displays new paths and highways, gives us new glimpses of distant scenery. This wonderful suggestiveness is itself one of the marks of a true theory, one of the signs by which we know that we are investigating the actual, existing truths of Nature, and that our symbols and formulæ are expressing facts quite independent of themselves, though decipherable only by their means. As for the other questions, it is very difficult to render intelligible, even to a mathematician, the kind of knowledge acquired by mathematical research in a new field until he has made himself acquainted with its processes and notation, and we cannot hope to find in the remote regions of an abstract science many results so simple and striking as to appeal forcibly to the imagination of those who are unfamiliar with its conceptions and ideas. It would seem, therefore, that the question, "To what is it all tending?" could never be answered in general terms. I do not think any mathematician could see his way to a reply, or even give definite meaning to the question. He might feel daring enough to predict the probable drift of his own subject, but he could scarcely get a broad-enough view to enable him to indulge his fancy with respect to more than a very minute portion of the field already open to mathematical investigation. To the outsider I am afraid that the subject will continue to present much the same appearance as it does now; it will always seem to be stretching out into limitless symbolic wastes, without producing any results at all commensurate with its expansion.

Instead of attempting to consider the general question of what may be expected to result from the progress of mathematical science, we may restrict ourselves to asking whether the great extension of the bounds of the subject which is taking place in our time will materially add to its powers as a weapon of research in the concrete subjects. This is a question of the highest interest, and one that cannot fail to have occupied the thoughts of every mathematician at some time or another in the course of his work. For my own part, I do not think that the bearing of the modern developments of mathematics upon the physical sciences is likely to be very direct or immediate. It would indeed be rash to assert that there is any branch of mathematics so abstract or so recondite that it might not at any moment find an application in some concrete subject; still it

seems to me that if the extension of the pure sciences could only be justified by the value of their applications, it is very doubtful whether a satisfactory plea for any further developments could be sustained. As a rule each subject involves its own ideas and its own special analysis, and it can only occasionally happen that analytical methods devised for the expression and development of one subject will be found to be appropriate for another. It is obvious also that the chance of such applications becomes less and less as we travel farther and farther from the elementary processes and methods which are common to all the exact sciences. There is a general resemblance of style running through much of the analysis required in the physical sciences, but there is no such resemblance in the case of the pure sciences, or between the pure and the physical sciences. It appears likely therefore that, in the future, the mathematical obstacles which present themselves in physical research will have to be overcome, as heretofore, by means of investigations undertaken for the purpose, and that analysis will continue to be enriched by conceptions and results, and even by whole subjects (such as spherical harmonies), which will be entirely due to the concrete sciences. Of course, it will sometimes happen that a differential equation or an integral has already been considered in connection with some other theory, or a whole body of analysis or geometry will suddenly be found to admit of a physical interpretation; but, after all, even the pure sciences themselves exert but an indirect effect upon the perfection of mathematical formulæ and processes, and we must be prepared to find that in general the requirements of physics have to be met by special analytical researches. Having now endeavoured to consider the proposed question impartially, and from a cold and rational standpoint, I cannot refrain from adding that, in spite of all I have said, I believe that every mathematician must cherish in his heart the conviction that at any moment some special analysis, devised in connection with a branch of pure mathematics, may bear wonderful fruit in one of the applied sciences, giving short and complete solutions of problems which could hitherto be treated only by prolix and cumbrous methods. For example, it is difficult to believe that the present unwieldy and imperfect treatment of the lunar theory is the most satisfactory that can be devised. We cannot but hope that some happy discovery in pure mathematics may replace the clumsy and tedious series of our day by simple and direct analytical methods exactly suited to the problem in question. In the different branches of pure mathematics, we find not infrequently that researches connected with one subject incidentally throw a flood of light upon another, and that we are thus led to solutions of problems and explanations of mysteries which would never have yielded to direct attack in the complete absence of any guide to the proper path to be pursued. So, too, in the lunar theory, if the direct attack should fail to supply any better treatment of the subject, we cannot but hope that some day the development of a new branch of mathematics, entirely unconnected with dynamics, may supply the key to the required method. It should be remembered also that dynamics, which differs from the pure sciences only by the inclusion of the laws of motion, is but little removed from them in the character of its more general problems.

It would seem at first sight as if the rapid expansion of the region of mathematics must be a source of danger to its future progress. Not only does the area widen, but the subjects of study increase rapidly in number, and the work of the mathematician tends to become more and more specialized. It is of course merely a brilliant exaggeration to say that no mathematician is able to understand the work of any other mathematician, but it is certainly true that it is daily becoming more and more difficult for a mathematician to keep himself acquainted, even in a general way, with the progress of any of the branches of mathematics except those which form the field of his own labours. I believe, however, that the increasing extent of the territory of mathematics will always be counteracted by increased facilities in the means of communication. Additional knowledge opens to us new principles and methods which may conduct us with the greatest ease to results which previously were most difficult of access; and improvements in notation may exercise the most powerful effects both in the simplification and accessibility of a subject. It rests with the worker in mathematics not only to explore new truths, but to devise the language by which they may be discovered and expressed; and the genius of a great mathematician displays itself no less in the notation he invents for deciphering his subject than in the results attained. There are some theories in which the notation seems to arise so simply and naturally out of the subject itself, that it is difficult to realize that it could have required any creative power to produce it; but it may well have happened that in these very cases it was the discovery of the appropriate notation which gave the subject its first real start, and rendered it amenable to effective treatment. When the principles that underlie a theory have been well grasped, the proper notation almost necessarily suggests itself, if it has not been already discovered; but some sort of provisional notation is required in the early stages of a theory in order to make any progress at all, and the mathematician who first gains a real insight into the nature of a subject is almost sure to be the first to seize upon the right notation. I have great faith in the power of well-chosen notation to simplify complicated theories and to bring remote ones near; and I think it is safe to predict that the increased knowledge of principles and the resulting improvements in the symbolic language of mathematics will always enable us to grapple satisfactorily with the difficulties arising from the mere extent of the subject.

Quite distinct from the theoretical question of the manner in which mathematics will rescue itself from the perils to which it is exposed by its own prolific nature is the practical problem of finding means of rendering available for the student the results which have been already accumulated, and making it possible for a learner to obtain some idea of the present state of the various departments of mathematics. This is a problem which is common to all rapidly moving branches of science, although the difficulties are increased in the case of mathematics by its wide extent and the comparative smallness of the audience addressed. The great mass of mathematical literature will be always contained in Journals and Transactions, but there is no reason why it should not be rendered far more useful and accessible than at present by means of treatises or higher text-books. The whole science suffers from want of avenues of approach, and many beautiful branches of mathematics are regarded as difficult and technical merely because they are not easily accessible. Ten years ago I should have said that even a bad treatise was better than none at all. I do not say that now, but I feel very strongly that any introduction to a new subject written by a competent person confers a real benefit on the whole science. The number of excellent text-books of an elementary kind that are published in this country makes it all the more to be regretted that we have so few that are intended for the more advanced student. As an example of the higher kind of text-book, the want of which is so badly felt in many subjects, I may mention the second part of Prof. Chrystal's "Algebra" published last year, which in a small compass gives a great mass of valuable and fundamental knowledge that has hitherto been beyond the reach of an ordinary student, though in reality lying so close at hand. I may add that in any treatise or higher text-book it is always desirable that references to the original memoirs should be given, and, if possible, short historical notices also. I am sure that no subject loses more than mathematics by any attempt to dissociate it from its history.

There is no more striking feature in the mathematical literature of our day than the numerous republications in a collected form of the writings of the greatest mathematicians. These collected editions not only set before us as a whole the complete works of the masters of our science, but they make it possible for others besides those who reside in the vicinity of large libraries to become acquainted with the principal contributions with which it has been enriched in our century; and, besides being of immense advantage to the science at large, they even go some way towards supplying the want of systematic introductions to the advanced subjects. Among these republications the collected edition of Cayley's works, now in course of publication by the University of Cambridge, is deserving of especial notice. By undertaking this great work, not only in the lifetime of its author, but while in the full vigour of his powers, the University has secured the inestimable advantage of his own editorship, and thus, under the very best auspices, the world is now being placed in full possession of this grand series of memoirs, which already cover a period of nearly fifty years.

Although it may not be possible to contemplate the actual position of pure mathematics in this country with any great amount of enthusiasm, we may yet feel some satisfaction in reflecting that there is more cause for congratulation at present than there has been at any time in the last hundred and fifty years, and that we are far removed from the state of affairs which existed before the days of Cayley and Sylvester. Unfortunately,

we cannot point with pride to any distinct school of the pure sciences corresponding to the Cambridge school of mathematical physics, and I am afraid that the old saying that we have generals without armies is as true as ever. For this there is no immediate remedy; a school must grow up gradually of itself, as the study of mathematical physics has grown up at Cambridge. I certainly should not wish, even if it were possible, to obtain more recruits for the pure sciences at the expense of the applied, nor do I desire to see the system of instruction which has found favour in this country so modified that pure mathematics could be carried on by narrow specialists. I should be sorry, for example, that a student, after learning algebra and differential calculus, should pass directly to the theory of curves, and devote himself to research in this field without ever having acquired a general knowledge of other branches of mathematics or of any of its applications. Every person who proposes to engage in mathematical research should be equipped at starting upon his career with some knowledge of at least all the subjects included in the first part of the Mathematical Tripos. From what I have said in an earlier portion of this address it may be inferred that, from the point of view of the pure mathematician, I think that the course of study, and some of the text-books, are capable of improvement, but I am satisfied that a general mathematical training such as the Tripos requires is of the greatest possible value to every student, and that without it he cannot even make a good decision as to the class of subjects to which he is likely to devote his labour with the best effect. If the student were brought by the shortest possible route to the frontier of one of the subjects, where a fruitful field of research was pointed out to him, there is no doubt that the amount of mathematical literature produced might be greatly increased, but I am sure that the advantage to science would not be proportional to this increased amount. I am convinced that no one should devote himself to the abstract sciences unless he feels strongly drawn to them by his tastes. These subjects are treated by means of a powerful symbolic language, and it is the business of the investigator to discriminate between equations and formulæ which represent valuable facts in Nature and those which are merely symbolic relations, deducible from others that are more fundamental, and having no special significance in the subject itself. The mathematician requires tact and good taste at every step of his work, and he has to learn to trust to his own instinct to distinguish between what is really worthy of his efforts and what is not; he must take care not to be the slave of his symbols, but always to have before his mind the realities which they merely serve to express. For these and other reasons it seems to me of the highest importance that a mathematician should be trained in no narrow school; a wide course of reading in the first few years of his mathematical study cannot fail to influence for good the character of the whole of his subsequent work.

Before leaving this part of my subject I should like to say a few words upon the subject of accuracy of form in the presentation of mathematical results. In other branches of science, where quick publication seems to be so much desired, there may possibly be some excuse for giving to the world slovenly or ill-digested work, but there is no such excuse in mathematics. The form ought to be as perfect as the substance, and the demonstrations as rigorous as those of Euclid. The mathematician has to deal with the most exact facts of Nature, and he should spare no effort to render his interpretation worthy of his subject, and to give to his work its highest degree of perfection. "*Pauca sed matura*" was Gauss's motto.

The Universities are the natural home of mathematics, and to them we chiefly owe its cultivation and encouragement. There is, however, one other much younger body whose services to our science should not be passed over in any survey of its present state—I mean the London Mathematical Society. Twenty-five years ago, upon its foundation, I think the most sanguine mathematician would scarcely have ventured to predict that it would so soon take the position that it has among the scientific institutions of the world. The continuous interest taken by its members in its meetings, and the number and value of the papers published by it, show how steadily the flame of mathematical inquiry is burning among us. I do not presume to assert that the interest taken in the pure sciences can be regarded as an index of the energy and power of a nation, but it is certain that mathematical research flourishes only in a vigorous community. The search after abstract truth for its own sake, without the smallest thought of practical application or return in any form, and the yearning desire to explore the unknown, are signs of the vitality of a people, which are among the first to disappear when decay begins.

In conclusion, I will refer in some detail to one special subject—the Theory of Numbers. It is much to be regretted that this great theory, perhaps the greatest and most perfect of all the mathematical theories, should have been so little cultivated in this country, and that no portion of it should ever have been included in an ordinary course of mathematical study. It may be said to date from the year 1801, when Gauss published his "Disquisitiones Arithmeticæ," so that it is nearly thirty years older than the Theory of Elliptic Functions, to which we may assign the date 1829, the year in which Jacobi's "Fundamenta Nova" appeared. But the latter theory has already found a congenial home among us, while the former is nowhere systematically studied, and is still without a text-book. The chapters in books upon Algebra which bear the title "Theory of Numbers" give a misleading idea of the nature of the subject, the results there given being mainly introductory lemmas of the simplest kind. The theory has nothing to do with arithmetic in the ordinary sense of the word, or numerical tables, or the representation of numbers by figures in the decimal system or otherwise. All its results are actual truths of the most fundamental kind, which must exist *in rerum naturâ*. Its principal branches are the theory of forms and the so-called complex theories. Such a proposition as that every prime number, which when divided by 4 leaves remainder 1, can always be expressed as the sum of two squares, and that this can be done in one way only, affords a good example of a very simple result in the theory of forms. It is entirely independent of any method of representing numbers, and merely asserts that if we have 5, 13, 17, 29, &c., things—let us say marbles, to fix the ideas—we can always succeed in so arranging them as to form them into two squares, and that for each number we can do this in but one way. Simple as such a theorem is to enunciate and comprehend, the demonstration is far from easy. This is characteristic of the whole subject; simple propositions, which we can easily discover by trial, and of the universal truth of which we can feel but little doubt, require for their demonstration a refined and intricate analysis, founded upon the most difficult and imaginative conceptions which mathematics has as yet attained to in its struggles to grapple with the actual problems of the worlds of thought and matter.

The theory of quantity consists of two distinct branches—one relating to discrete quantity, and the other to continuous quantity. To the latter branch belong algebra and all the ordinary subjects of pure mathematics; the former bears the name of the theory of numbers. Its truths are of the most absolute kind, involving only the notions of number and arrangement; in fact, if we imagine all the exact sciences ranged in order, it naturally takes its place at one end of the series. Different sciences appeal to different intellects with very different force, but there are some minds over which the absolute character of the fundamental truths that belong to this theory and the absolute precision of its methods exercise the strongest fascination, and excite an interest which neither the truths of geometry nor the most important discoveries depending upon the constitution of matter are capable of producing.

Many of the greatest masters of the mathematical sciences were first attracted to mathematical inquiry by problems relating to numbers, and no one can glance at the periodicals of the present day which contain questions for solution without noticing how singular a charm such problems still continue to exert. This interest in numbers seems implanted in the human mind, and it is a pity that it should not have freer scope in this country. The methods of the theory of numbers are peculiar to itself, and are not readily acquired by a student whose mind has for years been familiarized with the very different treatment which is appropriate to the theory of continuous magnitude; it is therefore extremely desirable that some portion of the theory should be included in the ordinary course of mathematical instruction at our Universities. From the moment that Gauss, in his wonderful treatise of 1801, laid down the true lines of the theory, it entered upon a new day, and no one is likely to be able to do useful work in any part of the subject who is unacquainted with the principles and conceptions with which he endowed it.

Undoubted the subject is a difficult and intricate one even in its elementary parts, but there can be but little doubt that when the processes which are now only read by specialists on their way to the border become more generally known and studied, they will be found to admit of great simplification. It is in fact a territory where there is quite as much scope for the mathe-

matician in simplifying what has been already won as in securing new conquests. I hope that the apathy of so many years may lead to a splendid awakening in this country, and that our past neglect of this most beautiful theory may be atoned for in the future by special devotion and appreciation.

SECTION D.

BIOLOGY.

OPENING ADDRESS BY PROF. A. MILNES MARSHALL, M.A., M.D., D.SC., F.R.S., PRESIDENT OF THE SECTION.

As my theme for this morning's address I have selected the development of animals. I have made this choice from no desire to extol one particular branch of biological study at the expense of others, nor through failure to appreciate or at least admire the work done and the results achieved in recent years by those who are attacking the great problems of life from other sides and with other weapons.

My choice is determined by the necessity that is laid upon me, through the wide range of sciences whose encouragement and advancement are the peculiar privilege of this Section, to keep within reasonable limits the direction and scope of my remarks; and is confirmed by the thought that, in addressing those specially interested in and conversant with biological study, your President acts wisely in selecting as the subject-matter of his discourse some branch with which his own studies and inclinations have brought him into close relation.

Embryology, referred to by the greatest of naturalists as "one of the most important subjects in the whole round of natural history," is still in its youth, but has of late years thriven so mightily that fear has been expressed lest it should absorb unduly the attention of zoologists, or even check the progress of science by diverting interest from other and equally important branches.

Nor is the reason of this phenomenal success hard to find. The actual study of the processes of development; the gradual building up of the embryo, and then of the young animal, within the egg; the fashioning of its various parts and organs; the devices for supplying it with food, and for ensuring that the respiratory and other interchanges are duly performed at all stages—all these are matters of absorbing interest. Add to these the extraordinary changes which may take place after leaving the egg, the conversion, for instance, of the aquatic gill-breathing tadpole—a true fish as regards all essential points of its anatomy—into a four-legged frog, devoid of tail, and breathing by lungs; or the history of the metamorphosis by which the sea-urchin is gradually built up within the body of its pelagic larva, or the butterfly derived from its grub. Add to these again the far wider interest aroused by comparing the life-histories of allied animals, or by tracing the mode of development of a complicated organ, *e.g.* the eye or the brain, in the various animal groups, from its simplest commencement, through gradually increasing grades of efficiency, up to its most perfect form as seen in the highest animals. Consider this, and it becomes easy to understand the fascination which embryology exercises over those who study it.

But all this is of trifling moment compared with the great generalization which tells us that the development of animals has a far higher meaning; that the several embryological stages and the order of their occurrence are no mere accidents, but are forced on an animal in accordance with a law, the determination of which ranks as one of the greatest achievements of biological science.

The doctrine of descent, or of evolution, teaches us that as individual animals arise, not spontaneously, but by direct descent from pre-existing animals, so also is it with species, with families, and with larger groups of animals, and so also has it been for all time; that as the animals of succeeding generations are related together, so also are those of successive geologic periods; that all animals, living or that have lived, are united together by blood relationship of varying nearness or remoteness; and that every animal now in existence has a pedigree stretching back, not merely for ten or a hundred generations, but through all geologic time since the dawn of life on this globe.

The study of development, in its turn, has revealed to us that each animal bears the mark of its ancestry, and is compelled to discover its parentage in its own development: that the phases through which an animal passes in its progress from the egg to the adult are no accidental freaks, no mere matters of developmental convenience, but represent more or less closely, in more or less modified manner, the successive ancestral stages through which the present condition has been acquired.

Evolution tells us that each animal has had a pedigree in the past. Embryology reveals to us this ancestry, because every animal in its own development repeats this history, climbs up its own genealogical tree.

Such is the recapitulation theory, hinted at by Agassiz, and suggested more directly in the writings of von Baer, but first clearly enunciated by Fritz Müller, and since elaborated by many, notably by Balfour and by Ernst Haeckel.

It is concerning this theory, which forms the basis of the science of embryology, and which alone justifies the extraordinary attention this science has received, that I venture to address you this morning.

A few illustrations from different groups of animals will best explain the practical bearings of the theory, and the aid which it affords to the zoologist of to-day; while these will also serve to illustrate certain of the difficulties which have arisen in the attempt to interpret individual development by the light of past history—difficulties which I propose to consider at greater length.

A very simple example of recapitulation is afforded by the eyes of the sole, plaice, turbot, and their allies. These "flat fish" have their bodies greatly compressed laterally; and the two surfaces, really the right and left sides of the animal, unlike, one being white, or nearly so, and the other coloured. The flat fish has two eyes, but these, in place of being situated, as in other fish, one on each side of the head, are both on the coloured side. The advantage to the fish is clear, for the natural position of rest of a flat fish is lying on the sea bottom, with the white surface downwards and the coloured one upwards. In such a position an eye situated on the white surface could be of no use to the fish, and might even become a source of danger, owing to its liability to injury from stones or other hard bodies on the sea bottom.

No one would maintain that flat fish were specially created as such. The totality of their organization shows clearly enough that they are true fish, akin to others in which the eyes are symmetrically placed one on each side of the head, in the position they normally hold among vertebrates. We must therefore suppose that flat fish are descended from other fish in which the eyes are normally situated.

The recapitulation theory supplies a ready test. On employing it, *i.e.* on studying the development of the flat fish, we obtain a conclusive answer. The young sole on leaving the egg is shaped just as an ordinary fish, and has the two eyes placed symmetrically on the two sides of the head. It is only after the young fish has reached some size, and has begun to approach the adult in shape, and to adopt its habit of resting on one side on the sea bottom, that the eye of the side on which it rests becomes shifted forwards, then rotated on to the top of the head, and finally twisted completely over to the opposite side.

The brain of a bird differs from that of other vertebrates in the position of the optic lobes, these being situated at the sides instead of on the dorsal surface. Development shows that this lateral position is a secondarily acquired one, for throughout all the earlier stages the optic lobes are, as in other vertebrates, on the dorsal surface, and only shift down to the sides shortly before the time of hatching.

Crabs differ markedly from their allies, the lobsters, in the small size and rudimentary condition of their abdomen or "tail." Development, however, affords abundant evidence of the descent of crabs from macrurous ancestors, for a young crab at what is termed the Megalopa stage has the abdomen as large as a lobster or prawn at the same stage.

Molluscs afford excellent illustrations of recapitulation. The typical gastropod has a large spirally-coiled shell; the limpet, however, has a large conical shell, which in the adult gives no sign of spiral twisting, although the structure of the animal shows clearly its affinity to forms with spiral shells. Development solves the riddle at once, telling us that in its early stages the limpet embryo has a spiral shell, which is lost on the formation, subsequently, of the conical shell of the adult.

Recapitulation is not confined to the higher groups of animals, and the Protozoa themselves yield most instructive examples. A very striking case is that of Orbitolites, one of the most complex of the porcellanous Foraminifera, in which each individual during its own growth and development passes through

the series of stages by which the cyclical or discoidal type o. shell was derived from the simpler spiral form.

In *Orbitolites tenuissima*, as Dr. Carpenter has shown,[1] "the whole transition is actually presented during the successive stages of its growth. For it begins life as a Cornuspira, ... its shell forming a continuous spiral tube, with slight interruptions at the points at which its successive extensions commence; while its sarcodic body consists of a continuous coil with slight constrictions at intervals. The second stage consists in the opening out of its spire, and the division of its cavity at regular intervals by transverse septa, traversed by separate pores, exactly as in Peneroplis. The third stage is marked by the subdivision of the 'peneropline' chambers into chamberlets, as in the early forms of Orbiculina. And the fourth consists in the exchange of the spiral for the cyclical plan of growth, which is characteristic of Orbitolites; a circular disk of progressively increasing diameter being formed by the addition of successive annular zones around the entire periphery."

The shells both of Foraminifera and of Mollusca afford peculiarly instructive examples for the study of recapitulation. As growth of the shell is effected by the addition of new shelly matter to the part already existing, the older parts of the shell are retained, often unaltered, in the adult; and in favourable cases, as in *Orbitolites tenuissima*, all the stages of development can be determined by simple inspection of the adult shell.

It is important to remember that the recapitulation theory, if valid, must apply not merely in a general way to the development of the animal body, but must hold good with regard to the formation of each organ or system, and with regard to the later equally with the earlier phases of development.

Of individual organs, the brain of birds has been already cited. The formation of the vertebrate liver as a diverticulum from the alimentary canal, which is at first simple, but by the folding of its walls becomes greatly complicated, is another good example; as is also the development of the vomer in amphibians as a series of toothed plates, equivalent morphologically to the placoid scales of fishes, which are at first separate, but later on fuse together and lose the greater number of their teeth.

Concerning recapitulation in the later phases of development and in the adult animal, the mode of renewal of the nails or of the epidermis generally is a good example, each cell commencing its existence in an indifferent form in the deeper layers of the epidermis, and gradually acquiring the adult peculiarities as it approaches the surface, through removal of the cells lying above it.

The above examples, selected almost haphazard, will suffice to illustrate the theory of recapitulation.

The proof of the theory depends chiefly on its universal applicability to all animals, whether high or low in the zoological scale, and to all their parts and organs. It derives, also, strong support from the ready explanation which it gives of many otherwise unintelligible points.

Of these latter a familiar and most instructive instance is afforded by rudimentary organs, *i.e.* structures which, like the outer digits of the horse's leg, or the intrinsic muscles of the ear of a man, are present in the adult in an incompletely developed form, and in a condition in which they can be of no use to their possessors; or else structures which are present in the embryo, but disappear completely before the adult condition is attained—for example, the teeth of whalebone whales, or the branchial clefts of all higher vertebrates.

Natural selection explains the preservation of useful variations, but will not account for the formation and perpetuation of useless organs; and rudiments such as those mentioned above would be unintelligible but for recapitulation, which solves the problem at once, showing that these organs, though now useless, must have been of functional value to the ancestors of their present possessors, and that their appearance in the ontogeny of existing forms is due to repetition of ancestral characters. Such rudimentary organs are, as Darwin pointed out, of larger relative or even absolute size in the embryo than in the adult, because the embryo represents the stage in the pedigree in which they were functionally active.

Rudimentary organs are extremely common, especially among the higher groups of animals, and their presence and significance are now well understood. Man himself affords numerous and excellent examples, not merely in his bodily structure, but by his speech, dress, and customs. For the silent letter *b* in the word doubt, or the *w* of answer, or the buttons on his elastic side boots are as true examples of rudiments, unintelligible but for their past history, as are the ear muscles he possesses but cannot use, or the gill-clefts, which are functional in fishes and tadpoles, and are present, though useless, in the embryos of all higher vertebrates, which in their early stages the hare and the tortoise alike possess, and which are shared with them by cats and by kings.

Another consideration of the greatest importance arises from the study of the fossil remains of the animals that formerly inhabited the earth. It was the elder Agassiz who first directed attention to the remarkable agreement between the embryonic growth of animals and their palæontological history. He pointed out the resemblance between certain stages in the growth of young fish and their fossil representatives, and attempted to establish, with regard to fish, a correspondence between their palæontological sequence and the successive stages of embryonic development. He then extended his observations to other groups, and stated his conclusions in these words:—[1] "It may therefore be considered as a general fact, very likely to be more fully illustrated as investigations cover a wider ground, that the phases of development of all living animals correspond to the order of succession of their extinct representatives in past geological times."

This point of view is of the utmost importance. If the development of an animal is really a repetition of its ancestral history, then it is clear that the agreement or parallelism which Agassiz insists on between the embryological and palæontological records must hold good. Owing to the attitude which Agassiz subsequently adopted with regard to the theory of natural selection, there is some fear of his services in this respect failing to receive full recognition, and it must not be forgotten that the sentence I have quoted was written prior to the clear enunciation of the recapitulation theory by Fritz Müller.

The imperfection of the geological record has been often referred to and lamented. It is very true that our museums afford us but fragmentary pictures of life in past ages; that the earliest volumes of the history are lost, and that of others but a few torn pages remain to us; but the later records are in far more satisfactory condition. The actual number of specimens accumulated from the more recent formations is prodigious; facilities for consulting them are far greater than they were; the international brotherhood of science is now fully established, and the fault will be ours if the material and opportunities now forthcoming are not rightly and fully utilized.

By judicious selection of groups in which long series of specimens can be obtained, and in which the hard skeletal parts, which alone can be suitably preserved as fossils, afford reliable indications of zoological affinity, it is possible to test directly this correspondence between palæontological and embryological histories, while in some instances a single lucky specimen will afford us, on a particular point, all the evidence we require.

Great progress has already been made in this direction, and the results obtained are of the most encouraging description.

By Alexander Agassiz a detailed comparison was made between the fossil series and the developmental stages of recent forms in the case of the Echinoids, a group peculiarly well adapted for such an investigation. The two records agree remarkably in many respects, more especially in the independent evidence they give as to the origin of the asymmetrical forms from more regular ancestors. The gradually increasing complication in some of the historic series is found to be repeated very closely in the development of their existing representatives; and with regard to the whole group, Agassiz concludes that,[2] "comparing the embryonic development with the palæontological one, we find a remarkable similarity in both, and in a general way there seems to be a parallelism in the appearance of the fossil genera and the successive stages of the development of the Echini."

Neumayr has followed similar lines, and by him, as by other authorities on the group, there seems to be general agreement as to the parallelism between the embryological and palæontological records, not merely for Echini, but for other groups of Echinodermata as well.

The Tetrabranchiate Cephalopoda are an excellent group in which to study the problem, for though no opportunity has yet occurred for studying the embryology of the only surviving mem-

[1] "On an Abyssal Type of the Genus Orbitolites," Phil. Trans., 1883, Part ii. p. 553.

[2] "Palæontological and Embryological Development." An Address before the American Association for the Advancement of Science, 1880.

ber of the group, the pearly nautilus, yet owing to the fact that growth of the shell is effected by addition of shelly matter to the part already present, and to the additions being made in such manner that the older part of the shell persists unaltered, it is possible, from examination of a single shell—and in the case of fossils the shells are the only part of which we have exact knowledge—to determine all the phases of its growth; just as in the shell of Orbitolites all the stages of development are manifest on inspection of an adult specimen.

In such a shell as nautilus or ammonites the central chamber is the oldest or first formed one, to which the remaining chambers are added in succession. If, therefore, the development of the shell is a repetition of ancestral history, the central chamber should represent the palæontologically oldest form, and the remaining chambers in succession forms of more and more recent origin. Ammonite shells present, more especially in their sutures, and in the markings and sculpturing of their surface, characters that are easily recognized, and readily preserved in fossils; and the group, consequently, is a very suitable one for investigation from this standpoint.

Würtenberger's admirable and well-known researches[1] have shown that in the Ammonites such a correspondence between historic and embryonic development does really exist; that, for example, in Aspidoceras the shape and markings of the shells in young specimens differ greatly from those of adults, and that the characters of the young shells are those of palæontologically older forms.

Another striking illustration of the correspondence between the palæontological and developmental records is afforded by the antlers of deer, in which the gradually increasing complication of the antler in successive years agrees singularly closely with the progressive increase in size and complexity shown by the fossil series from the Miocene age to recent times.

Of cases where a single specimen has sufficed to prove the palæontological significance of a developmental character, Archæopteryx affords a typical example. In recent birds the metacarpals are firmly fused with one another, and with the distal series of carpals; but in development the metacarpals are at first, and for some time, distinct. In Archæopteryx this distinctness is retained in the adult, showing that what is now an embryonic character in recent birds was formerly an adult one.

Other examples might easily be quoted, but these will suffice to show that the relation between palæontology and embryology, first enunciated by Agassiz, and required by the recapitulation theory, does in reality exist. There is much yet to be done in this direction. A commencement, a most promising commencement, has been made, but as yet only a few groups have been seriously studied from this standpoint.

It is a great misfortune that palæontology is not more generally and more seriously studied by men versed in embryology, and that those who have so greatly advanced our knowledge of the early development of animals should so seldom have tested their conclusions as to the affinities of the groups they are concerned with by direct reference to the ancestors themselves, as known to us through their fossil remains.

I cannot but feel that, for instance, the determination of the affinities of fossil Mammalia, of which such an extraordinary number and variety of forms are now known to us, would be greatly facilitated by a thorough and exact knowledge of the development, and especially the later development, of the skeleton in their existing descendants, and I regard it as a reproach that such exact descriptions of the later stages of development should not exist, even in the case of our commonest domestic animals.

The pedigree of the horse has attracted great attention, and has been worked at most assiduously, and we are now, largely owing to the labours of American palæontologists, able to refer to a series of fossil forms commencing in the lowest Eocene beds, and extending upwards to the most recent deposits, which show a complete gradation from a more generalized mammalian type to the highly specialized condition characteristic of the horse and its allies, and which may reasonably be regarded as indicating the actual line of descent of the horse. In this particular case, more frequently cited than any other, the evidence is entirely palæontological. The actual development of the horse has yet to be studied, and it is greatly to be desired that it should be undertaken speedily. Klever's[2] recent work on the development of the teeth in the horse may be referred to as showing that important and unexpected evidence is to be obtained in this way.

A brilliant exception to the statement just made as to the want of exact knowledge of the later development of the more highly organized animals is afforded by the splendid labours of Prof. Kitchen Parker, whose recent death has deprived zoology of one of her most earnest and single-minded students, and zoologists, young and old alike, of a true and sincere friend. Prof. Parker's extraordinarily minute and painstaking investigations into the development of the vertebrate skull rank among the most remarkable of zootomical achievements, and afford a rich mine of carefully recorded facts, the full value and bearing of which we are hardly yet able to appreciate.

If further evidence as to the value and importance of the recapitulation theory were needed, it would suffice to refer to the influence which it has had on the classification of the animal kingdom. Ascidians and Cirripedes may be quoted as important groups, the true affinities of which were first revealed by embryology; and in the case of parasitic animals the structural modifications of the adult are often so great that but for the evidence yielded by development their zoological position could not be determined. It is now indeed generally recognized that in doubtful cases embryology affords the safest of all clues, and that the zoological position of such forms can hardly be regarded as definitely established unless their development, as well as their adult anatomy, is ascertained.

It is owing to this recapitulation theory that embryology has exercised so marked an influence on zoological speculation. Thus the formation in most, if not in all, animals of the nervous system and of the sense organs from the epidermal layer of the skin, acquired a new significance when it was recognized that this mode of development was to be regarded as a repetition of the primitive mode of formation of such organs; while the vertebral theory of the skull affords a good example of a view, once stoutly maintained, which received its death-blow through the failure of embryology to supply the evidence requisite in its behalf. The necessary limits of time and space forbid that I should attempt to refer to even the more important of the numerous recent discoveries in embryology, but mention may be very properly made here of Sedgwick's determination of the mode of development of the body cavity in Peripatus, a discovery which has thrown most welcome light on what was previously a great morphological puzzle.

We must now turn to another side of the question. Although it is undoubtedly true that development is to be regarded as a recapitulation of ancestral phases, and that the embryonic history of an animal presents to us a record of the race history, yet it is also an undoubted fact, recognized by all writers on embryology, that the record so obtained is neither a complete nor a straightforward one.

It is indeed a history, but a history of which entire chapters are lost, while in those that remain many pages are misplaced, and others are so blurred as to be illegible; words, sentences, or entire paragraphs are omitted, and worse still, alterations or spurious additions have been freely introduced by later hands, and at times so cunningly as to defy detection.

Very slight consideration will show that development cannot in all cases be strictly a recapitulation of ancestral stages. It is well known that closely allied animals may differ markedly in their mode of development. The common frog is at first a tadpole, breathing by gills, a stage which is entirely omitted by the West Indian Hylodes. A crayfish, a lobster, and a prawn are allied animals, yet they leave the egg in totally different forms. Some developmental stages, as the pupa condition of insects, or the stage in the development of a dogfish in which the œsophagus is imperforate, cannot possibly be ancestral stages. Or again, a chick embryo of say the fourth day is clearly not an animal capable of independent existence, and therefore cannot correctly represent any ancestral condition, an objection which applies to the developmental history of many, perhaps of most animals.

Haeckel long ago urged the necessity of distinguishing in actual development between those characters which are really historical and inherited, and those which are acquired or spurious additions to the record. The former he termed palingenetic or ancestral characters, the latter cenogenetic or acquired. The distinction is undoubtedly a true one, but an exceedingly difficult one to draw in practice. The causes which

[1] "Studien über die Stammesgeschichte der Ammoniten. Ein geologischer Beweis für die Darwin'sche Theorie" (Leipzig, 1880.)

[2] "Zur Kenntniss der Morphogenese des Equidengebisses," [*Morphologisches Jahrbuch*, xv., 1889, p. 308.

prevent development from being a strict recapitulation of ancestral characters, the mode in which these came about, and the influence which they respectively exert, are matters which are greatly exercising embryologists, and the attempt to determine which has as yet met with only partial success.

The most potent and the most widely spread of these disturbing causes arise from the necessity of supplying the embryo with nutriment. This acts in two ways. If the amount of nutritive matter within the egg is small, then the young animal must hatch early, and in a condition in which it is able to obtain food for itself. In such cases there is of necessity a long period of larval life, during which natural selection may act so as to introduce modifications of the ancestral history, spurious additions to the text.

If, on the other hand, the egg contain within itself a considerable quantity of nutrient matter, then the period of hatching can be postponed until this nutrient matter has been used up. The consequence is that the embryo hatches at a much later stage of its development, and if the amount of food-material is sufficient, may even leave the egg in the form of the parent. In such cases the earlier developmental phases are often greatly condensed and abbreviated; and as the embryo does not lead a free existence, and has no need to exert itself to obtain food, it commonly happens that these stages are passed through in a very modified form, the embryo being, as in a four-day chick, in a condition in which it is clearly incapable of independent existence.

The nutrition of the embryo prior to hatching is most usually effected by granules of nutrient matter, known as food yolk, and embedded in the protoplasm of the egg itself; and it is on the relative abundance of these granules that the size of the egg chiefly depends.

Large size of eggs implies diminution of number of the eggs, and hence of the offspring; aud it can be well understood that while some species derive advantage in the struggle for existence by producing the maximum number of young, to others it is of greater importance that the young on hatching should be of considerable size and strength, and able to begin the world on their own account. In other words, some animals may gain by producing a large number of small eggs, others by producing a smaller number of eggs of larger size—*i.e.* provided with more food yolk.

The immediate effect of a large amount of food yolk is to mechanically retard the processes of development; the ultimate result is to greatly shorten the time occupied by development. This apparent paradox is readily explained. A small egg, such as that of Amphioxus, starts its development rapidly, and in about eighteen hours gives rise to a free-swimming larva, capable of independent existence, with a digestive cavity and nervous system already formed; while a large egg, like that of the hen, hampered by the great mass of food yolk by which it is distended, has, in the same time, made but very slight progress.

From this time, however, other considerations begin to tell. Amphioxus has been able to make this rapid start owing to its relative freedom from food yolk. This freedom now becomes a retarding influence, for the larva, containing within itself but a very scanty supply of nutriment, must devote much of its energies to hunting for, and to digesting its food, and hence its further development will proceed more slowly.

The chick embryo, on the other hand, has an abundant supply of food in the egg itself; it has no occasion to spend time searching for food, but can devote its whole energies to the further stages of its development. Hence, except in the earliest stages, the chick develops more rapidly than Amphioxus, and attains its adult form in a much shorter time.

The tendency of abundant food yolk to lead to shortening or abbreviation of the ancestral history, and even to the entire omission of important stages, is well known. The embryo of forms well provided with yolk takes short cuts in its development, jumps from branch to branch of its genealogical tree, instead of climbing steadily upwards.

Thus the little West Indian frog, Hylodes, produces eggs which contain a larger amount of food yolk than those of the common English frog. The young Hylodes is consequently enabled to pass through the tadpole stage before hatching—to attain the form of a frog before leaving the egg; and the tadpole stage is only imperfectly recapitulated, the formation of gills, for instance, being entirely omitted.

The influence of food yolk on the development of animals is closely analogous to that of capital in human undertakings. A new industry, for example that of pen-making, has often been started by a man working by hand and alone, making and selling his own wares; if he succeed in the struggle for existence, it soon becomes necessary for him to call in others to assist him, and to subdivide the work; hand labour is soon superseded by machines, involving further differentiation of labour; the earlier machines are replaced by more perfect and more costly ones; factories are built, agents engaged, and, in the end, a whole army of work-people employed. In later times a man commencing business with very limited means will start at the same level as the original founder, and will have to work his way upwards through much the same stages, *i.e.* will repeat the pedigree of the industry. The capitalist, on the other hand, is enabled, like Hylodes, to omit these earlier stages, and, after a brief period of incubation, to start business with large factories equipped with the most recent appliances, and with a complete staff of work-people, *i.e.* to spring into existence fully fledged.

There is no doubt that abundance of food-yolk is a direct and very frequent cause of the omission of ancestral stages from individual development; but it must not be viewed as a sole cause. It is quite impossible that any animal, except perhaps in the lowest zoological groups, should repeat all the ancestral stages in the history of the race; the limits of time available for individual development will not permit this. There is a tendency in all animals towards condensation of the ancestral history—towards striking a direct path from the egg to the adult.

This tendency is best marked in the higher, the more complicated members of a group; *i.e.* in those which have a longer and more tortuous pedigree; and though greatly strengthened by the presence of food yolk in the egg, is apparently not due to this in the first instance.

Thus the simpler forms of Orbitolites, as *O. tenuissima*, repeat in their development all the stages leading from a spiral to a cyclical shell; but in the more complicated species, as Dr. Carpenter has pointed out, there is a tendency towards precocious development of the adult characters, the earlier stages being hurried over in a modified form; while in the most complex examples, as in *O. complanata*, the earlier spiral stages may be entirely omitted, the shell acquiring almost from its earliest commencement the cyclical mode of growth. There is no question here of relative abundance of food yolk, but merely of early or precocious appearance of adult characters.

The question of the relations and influence of food yolk, involving as it does the larger or smaller size of the egg, is, however, merely a special side of the much wider question of the nutrition of the embryo, one of the most potent of the disturbing elements affecting development.

Speaking generally, we may say that large eggs are more often met with in the higher than the lower groups of animals. Birds and reptiles are cases in point, and, if mammals do not now produce large eggs, it is because a more direct and more efficient mode of nourishing the young by the placenta has been acquired by the higher forms, and has replaced the food yolk that was formerly present, and is now retained in quantity by Monotremes alone. Molluscs afford another good example, the eggs of Cephalopoda being of larger size than those of the less highly organized groups.

The large size of the eggs of Elasmobranchs, and perhaps that of Cephalopods also, may possibly be associated with the carnivorous habits of the animals; for it is of importance that forms which prey on other animals should hatch of considerable size and strength.

The influence of habitat must also be considered. It has long been noticed as a general rule that marine animals lay small eggs, while their fresh-water allies have eggs of much larger size. The eggs of the salmon or trout are much larger than those of the cod or herring; and the crayfish, though only a quarter the length of a lobster, lay eggs of actually larger size.

This larger size of the eggs of fresh-water forms appears to be dependent on the nature of the environment to which they are exposed. Considering the geological instability of the land as compared with the ocean, there can be no doubt that the fresh-water fauna is, speaking generally, derived from the marine fauna; and the great problem with regard to fresh-water life is to explain why it is that so many groups of animals which flourish abundantly in the sea should have failed to establish themselves in fresh water. Sponges and Cœlenterates abound in the sea, but their fresh-water representatives are extremely few in number; Echinoderms are exclusively marine: there are

no fresh-water Cephalopods, and no Ascidians; and of the smaller groups of Worms, Molluscs, and Crustaceans, there are many that do not occur in fresh-water.

Direct experiment has shown that in many cases this distribution is not due to inability of the adult animals to live in fresh water; and the real explanation appears to be that the early larval stages are unable to establish themselves under such conditions. This interesting suggestion, which has been worked out in detail by Prof. Sollas,[1] undoubtedly affords an important clue. To establish itself permanently in fresh water an animal must either be fixed, or else be strong enough to withstand and make headway against the currents of the streams or rivers it inhabits, for otherwise it will in the long run be swept out to sea, and this consideration applies to larval forms equally with adults.

The majority of marine invertebrates leave the egg as minute ciliated larvæ; and such larvæ are quite incapable of holding their own in currents of any strength. Hence, it is only forms which have got rid of the free-swimming ciliated larval stage, and which leave the egg of considerable size and strength, that can establish themselves as fresh-water animals. This is effected most readily by the acquisition of food yolk—hence the large size of the eggs of fresh-water animals—and is often supplemented, as Sollas has shown, by special protective devices of a most interesting nature. For this reason fresh-water forms are not so well adapted as their marine allies for the study of ancestral history as revealed in larval or embryonic development.

Before leaving the question of food yolk, reference must be made to the proposal of the brothers Sarasin, to regard the yolk cells as forming a distinct embryonic layer, the lecithoblast,[2] distinct from the blastoderm. I do not desire to speak dogmatically on a point the full bearings of which are not yet apparent, but I venture to think that this suggestion will not commend itself to embryologists. The distinction between the yolk granules and the cells in which they are embedded is a real and fundamental one; but I see no reason for regarding the yolk cells as other than originally functional endoderm cells in which yolk granules have accumulated to such an extent that they have in extreme cases become devoted solely to the storing of food for the embryo.[3]

Of all the causes tending to modify development, tending to obscure or falsify the ancestral record, food yolk is the most frequent and the most important; its position in the egg determines the mode of segmentation; and its relative abundance affects profoundly the entire embryonic history, and decides at what particular stage, and of what size and form, the embryo shall hatch.

The loss of food yolk is another disturbing element, the full influence of which is as yet imperfectly understood, but the possibility of which must be always kept in mind. It is best known in the case of mammals, where it has led to apparent, though very deceptive, simplification of development; and it will probably not be until the embryology of the large-yolked Monotremes is at length described, that we shall fully understand the formation of the germinal layers in the higher placental mammals.

Amongst invertebrates we know but little as yet concerning the effects of loss of food yolk. It has been suggested that the extraordinary nature of the segmentation of the egg of *Peripatus capensis*, made known to us through Mr. Sedgwick's admirable researches, may be due to loss of food yolk; a suggestion which receives support from the long duration of uterine development in this case.

Our knowledge is very imperfect as to the ease with which food yolk may be acquired or lost; but until our information is more precise on this point, it seems unwise to lay much stress on suggested pedigrees which involve great and frequent alternations in the amount of food yolk present.

Of causes other than food yolk, or only indirectly connected with it, which tend to falsify the ancestral history, many are now known, but time will only permit me to notice the more important. These are distortion, whether in time or space; sudden or violent metamorphosis; a series of modifications, due chiefly to mechanical causes, and which may be spoken of as developmental conveniences; the important question of variability in development; and finally the great problem of degeneration.

Concerning distortions in time, all embryologists have noticed the tendency to anticipation or precocious development of characters which really belong to a later stage in the pedigree. The early attainment of the cyclical form in the shell of *Orbitolites complanata* is a case in point; and Würtemberger has specially noticed this tendency in Ammonites. Many early larvæ show it markedly, the explanation in this case being that it is essential for them to hatch in a condition capable of independent existence, *i.e.* capable, at any rate, of obtaining and digesting their own food.

Anachronisms, or actual reversal of the historical order of development of organs or parts, occur frequently. Thus the joint surfaces of bones acquire their characteristic curvatures before movement of one part on another is effected, and before even the joint cavities are formed.

Another good example is afforded by the development of the mesenterial filaments in Alcyonarians. Wilson has shown in the case of Renilla that in the development of an embryo from the egg the six endodermal filaments appear first, and the two long ectodermal filaments at a later period; but that in the formation of a bud this order of development is reversed, the ectodermal filaments being the first formed. He suggests, in explanation, that, as the endodermal filaments are the digestive organs, it is of primary importance to the free embryo that they should be formed quickly. The long ectodermal filaments are chiefly concerned with maintaining currents of water through the colony; in bud-development they appear before the endodermal filaments, because they enable the bud during its early stages to draw nutrient matter from the body fluid of the parent; while the endodermal filaments cannot come into use until the bud has acquired both mouth and tentacles.

The completion of the ventricular septum in the heart of higher vertebrates before the auricular septum is a well-known anachronism, and every embryologist could readily furnish many other cases.

A curious instance is afforded by the development of the teeth in mammals, if recent suggestions as to the origin of the milk dentition are confirmed, and the milk dentition prove to be a more recent acquisition than the permanent one.[1]

But the most important cases in reference to distortion in time concern the reproductive organs. If development were a strict and correct recapitulation of ancestral history, then each stage would possess reproductive organs in a mature condition. This is not the case, and it is clearly of the greatest importance that it should not be. It is true that the first commencement of the reproductive organs may occur at a very early larval stage, or even that the very first step in development may be a division of the egg into somatic and reproductive cells; and it is possible that, as maintained by Weismann, this latter condition is a primitive one. Still, even in these cases the reproductive organs merely commence their development at these early stages, and do not become functional until the animal is adult.

Exceptionally in certain animals, and as a normal occurrence in others, precocious maturation of the reproductive organs takes place, and a larval form becomes capable of sexual reproduction. This may lead to arrest of development, either at a late larval period, as in the Axolotl, or at successively earlier and earlier stages, as in the gonophores of the Hydromedusæ, until finally the extreme condition seen in Hydra is produced.

We do not know the causes that determine the period, whether late or early, at which the reproductive organs ripen, but the question is one of great interest and importance and deserves careful attention. The suggestion has been made that entire groups of animals, such as the Mesozoa, are merely larvæ, arrested through such precocious acquiring of reproductive power, and it is conceivable that this may be the case. Mesozoa are a puzzling group in which the life-history, though known with tolerable completeness, has as yet given us no reliable clue concerning their affinities to other animals—a tantalizing distinction that is shared with them by Rotifers and Polyzoa.

Distortion of a curious kind is seen in cases of abrupt metamorphosis, where, as in the case of many Echinoderms, of Phoronis, and of the metabolic insects, the larva and the adult differ greatly in form, habits, mode of life, and very usually in

[1] "On the Origin of Freshwater Faunas," Scientific Transactions of the Royal Dublin Society, vol. iii. Ser. 11, 1886.

[1] *Cf.* Thomas Oldfield, "On the Homologies and Succession of the Teeth in the Dasyuridæ, with an attempt to trace the history of the evolution of the Mammalian teeth in general," Phil. Trans., 1887.

the nature of their food and the mode of obtaining it; and the transition from one stage to the other is not a gradual but an abrupt one, at any rate so far as external characters are concerned.

Sudden changes of this kind, as from the free-swimming Pluteus to the creeping Echinus, or from the sluggish leaf-eating caterpillar to the dainty butterfly, cannot possibly be recapitulatory, for even if small jumps are permissible in Nature, there is no room for bounds forward of this magnitude. Cases of abrupt metamorphosis may always be viewed as due to secondary modifications, and rarely, if ever, have any significance beyond the particular group of animals concerned. For example, a Pluteus larva may be recognized as belonging to the group of Echinoidea before the adult urchin has commenced to be formed within it, and the Lepidopteran caterpillar is already an unmistakable insect. Hence, for the explanation of the metamorphoses in these cases it is useless to look outside the groups of Echinoidea and Insecta respectively.

Abrupt metamorphosis is always associated with great change in external form and appearance, and in mode of life, and very usually in mode of nutrition. A gradual transition in such cases is inadmissible, because in the intermediate stages the animal would be adapted to neither the larval nor the adult condition; a gradual conversion of the biting mouth parts of the caterpillar to the sucking proboscis of a moth would inevitably lead to starvation. The difficulty is evaded by retaining the external form and habits of one particular stage for an unduly long period, so that the relations of the animal to the surrounding environment remain unchanged, while internally preparations for the later stages are in progress. Cinderella and the princess are equally possible entities, each being well adapted to her environment. The exigencies of the situation do not permit, however, of a gradual change from one to the other: the transformation, at least as regards external appearance, must be abrupt.

Kleinenberg has recently directed attention to cases in which the larval and adult organs develop independently; the larval nervous system, for instance, aborting completely and forming no part of that of the adult. I am not sure that I fully understand Kleinenberg's argument, but it seems very possible that such cases, which are probably far more numerous than is yet admitted, may be due to what may be termed the telescoping of ancestral stages one within another, which takes place in actual development, and may accordingly be grouped under the head of developmental convenience. Undue prolongation of an early ancestral stage, as in cases of abrupt metamorphosis, must involve modification, especially in the muscular and nervous systems; in such cases a telescoping of ancestral stages takes place, as we have seen, the adult being developed within the larva. Such telescoping must distort the recapitulatory history, and as the shape of the larva and adult may differ widely, an independent origin of organs, especially the muscular and nervous systems, may be acquired secondarily.

The stage in the development of Squilla, in which the three posterior maxillipedes disappear completely, to reappear at a later stage in a totally different form, is not to be interpreted as meaning that the adult maxillipedes are entirely new structures unconnected historically with those of the larva. Neither is the annual shedding of the antlers of deer to be regarded as the repetition of an ancestral hornless condition intercalated historically between successive stages provided with antlers. In both cases the explanation is afforded by convenience, whether of the embryo or adult.

Many embryological modifications or distortions may be attributed to mechanical causes, and may fairly be considered under the head of developmental conveniences.

The amnion of higher vertebrates is a case in point, and is probably rightly explained as due in the first instance to sinking or depression of the embryo into the yolk, in order to avoid distortion through pressure against a hard unyielding eggshell. A similar device is employed, presumably for the same reason, in the early development of many insect embryos; and the depression of the Tænia head within the cyst is a phenomenon of very similar nature.

Restriction of the space within which development occurs often causes displacement or distortion of organs, whose growth, restricted in its normal direction, takes place along the lines of least resistance. The telescoping of the limbs and other organs within the body of an insect larva is a simple case of such distortion; and a more complicated example, closely comparable in many ways to the invagination of the Tænia head, is afforded by the remarkable inversion of the germinal layers in rodents, first described by Bischoff in the guinea-pig, and long believed to be peculiar to that animal, but subsequently and simultaneously discovered by three independent observers—Kupffer, Selenka, and Fraser—to occur in varying degrees in rats, mice, and in other rodents.

One of the most recent attempts to explain developmental peculiarities as due to mechanical causes is Mr. Dendy's suggestion with regard to the pseudogastrula stage in the development of the calcareous sponges. It is well known that, while the larva is in the amphiblastula stage, and still embedded in the tissues of the parent, the granular cells become invaginated within the ciliated cells, giving rise to the pseudogastrula stage. At a slightly later stage, when the larva becomes free, the invaginated granular cells become again everted, and the larva spherical in shape; while still later invagination occurs once more, the ciliated cells being this time invaginated within the granular cells. The significance of the pseudogastrula stage has hitherto been undetermined, but Mr. Dendy points out that the larva always occupies a definite position with reference to the parental tissues; that the ciliated half of the larva is covered by a soft and yielding wall, while the opposite half, composed of the granular cells, is covered by a layer stiffened with rigid spicules; and his observations on the growth of the larva lead him to think that the pseudogastrula stage is brought about mechanically by flattening of the granular cells through pressure against this rigid wall of spicules.

Embryology supplies us with many unsolved problems, and it is not to be wondered at that this should be the case. Some of these may fairly be spoken of as mere curiosities of development, while others are clearly of greater moment. I do not propose to catalogue these, but will merely mention two or three which I happen to have recently run my head against, and remember vividly.

The solid condition of the œsophagus, in Elasmobranch embryos, first noticed by Balfour, is a very curious point. The œsophagus has at first a well-developed lumen, like the rest of the alimentary canal; but at an early period, stage K of Balfour's nomenclature, the part of the œsophagus overlying the heart, and immediately behind the branchial region, becomes solid, and remains solid for a long time, the exact date of reappearance of the lumen not being yet ascertained.

Mr. Bles and myself have recently noticed that a similar solidification of the œsophagus occurs in tadpoles of the common frog. In young free-swimming tadpoles the œsophagus is perforate, but in tadpoles of about 7½ mm. length it becomes solid and remains so until a length of about 10½ mm. has been attained. The solidification occurs at a stage closely corresponding with that in which it first appears in the dogfish, and a curious point about it is that in the frog the œsophagus becomes solid just before the mouth opening is formed, and remains solid for some little time after this important event.

This closing of the œsophagus clearly cannot be recapitulation, but the fact that it occurs at corresponding periods in the frog and dogfish suggests that it may possibly, as Balfour hinted, "turn out to have some unsuspected morphological bearing."

Another developmental curiosity is the duplication of the gill-slits by growth downwards of tongues from their dorsal margins; a duplication which is described as occurring in Amphioxus and in Balanoglossus, but in no other animal; and the occurrence of which, in apparently closely similar fashion, is one of the strongest arguments in favour of a real affinity between these two forms. It is hardly possible that such a modification should have been acquired independently twice over.

A much more litigious question is the significance of the neurenteric canal of vertebrates, that curious tubular communication between the central canal of the nervous system and the hinder end of the alimentary canal that is conspicuously present in the embryos of lower vertebrates, and retained in a more or less disguised condition in the higher groups as well.

The neurenteric canal was discovered by that famous embryologist Kowalevsky in Ascidians and in Amphioxus. He drew special attention to the occurrence of a stage in both Ascidians and in Amphioxus in which the larva is free-swimming and in which the sole communication between the alimentary cavity and the exterior is through the neurenteric canal and the central canal of the nervous system; and suggested[1] that animals may

[1] "Weitere Studien über die Entwickelungs-Geschichte des *Amphioxus lanceolatus*" (*Archiv für mikroskopische Anatomie*, Bd. xiii., 1877, p. 201).

have existed or may still exist in which the nerve tube fulfilled a non-nervous function, and possibly acted as part of the alimentary canal, a suggestion that has recently been revived in a somewhat extravagant form.

A passage of food particles into the alimentary cavity through the neural tube has not yet been seen, and probably does not occur, as the larva still possesses sufficient food yolk to carry it on in its development. It is therefore permissible to hold that the neurenteric canal may be a mere embryological device, and devoid of any deep morphological significance.

The question of variation in development is one of very great importance, and has perhaps not yet received the attention it deserves. We are in some danger of assuming tacitly that the mode of development of allied animals will necessarily agree in all important respects or even in details, and that if the development of one member of a group be known, that of the others may be assumed to be similar. The more recent progress of embryology is showing us that such inferences are not safe, and that in allied genera or species, or even in different individuals of the same species, variations of development may occur affecting important organs and at almost any stage in their formation.

Great individual variations in the earliest processes of development, *i.e.* the segmentation of the egg, have been described by different writers.

In Renilla, Wilson found an extraordinary range of variation in the segmentation of eggs from which apparently identical embryos were produced. In some cases the egg divided into two in the normal manner; in other cases it divided at once into eight, sixteen, or thirty-two segments, which in different specimens were approximately equal or markedly unequal in size. Sometimes a preliminary change of form occurred without any further result, the egg returning to its spherical shape, and pausing for a time before recommencing the attempt to segment. Segmentation sometimes commenced at one pole, as in telolecithal eggs, with the formation of four or five small segments, the rest of the egg breaking up later, either simultaneously or progressively, into segments about equal in size to those first formed; while lastly, in some instances segmentation was very irregular, following no apparent law.

It is noteworthy that the variability in the case of Renilla is apparently confined to the earliest stages, for whatever the mode of segmentation, the embryos in their later stages were indistinguishable from one another.

Similar modifications in the segmentation of the egg have been described in the oyster by Brooks, in Anodon and other Mollusca, in Hydra, and in Lumbricus, in which last Wilson has recently shown that marked differences occur in the eggs even of the same individual animal. In the different species of Peripatus there appear also to be considerable variations in the details of segmentation.

In the early embryonic stages after the completion of segmentation very considerable variation may occur in allied species or genera. Among Cœlenterates, for instance, the mode of formation of the hypoblast presents most perplexing modifications: it may arise as a true gastrula invagination; as cells budded off from one pole of the blastula into its cavity; as cells budded off from various parts of the wall of the blastula; by delamination or actual division of each cell of the blastula wall; or it may be present from the start as a solid mass of cells inclosed by the epiblast cells. It is in connection with these variations that controversy has arisen as to the primitive mode of development of the gastrula, a point to which I shall return later on.

Among the higher Metazoa or Cœlomata the extraordinary modifications in the position and in every conceivable detail of formation of the mesoblast in different and often in closely allied forms have given rise to ardent discussion, and have led to the proposal of theory after theory, each rejected in turn as only affording a partial explanation, and now culminating in Kleinenberg's protest against the use of the term mesoblast at all, at any rate in a sense implying any possibility of comparison with the primary layers, epiblast and hypoblast, of Cœlenterata.

This is not the place to attempt to decide so difficult and technical a point, even were I capable of so doing, but we may well take warning from this extraordinary diversity of development, the full extent of which I believe we as yet realize most imperfectly, that in our attempts to reconstruct ancestral history from ontogenetic development we have taken in hand no light task. To reconstruct Latin from modern European languages would in comparison be but child's play.

Of the readiness with which special developmental characters are acquired by allied animals the brothers Sarasin [1] have given us evidence in the extraordinary modifications presented by the embryonic and larval respiratory organs of Amphibians.

Confining ourselves to those forms which do not lay their eggs in water, and in which consequently development takes place within the egg, we find that Ichthyophis and Salamandra have three pairs of specially modified external gills. Nototrema has two pairs; Alytes and Typhlonectes have only a single pair, which in the latter genus take the form of enormous leaf-like outgrowths from the sides of the neck. In Hylodes and Pipa there are no gills, the tail acting as the larval respiratory organ; and in *Rana opisthodon*, according to Boulenger, larval respiration is effected by nine pairs of folds of the skin of the ventral surface of the body.

Most of these extraordinarily diversified organs are clearly secondarily acquired structures; it is possible that they all are, and that external gills, as was suggested by Balfour for Elasmobranchs, are to be regarded as embryonal respiratory organs acquired by the larvæ, and of no ancestral value. The point, however, cannot be considered settled, for on this view the external gills of Elasmobranchs and Amphibians would be independently acquired and not homologous structures, a view contradicted by the close agreement in their relations in the two groups, as well as by the absence of any real break between external and internal gills in Amphibians.

It is well known that the frog and the newt differ greatly in important points of their development. The two-layered condition of the epiblast in the frog is a marked point of difference, which involves further changes in the mode of formation of the nervous system and sense organs. The kidneys and their ducts differ considerably in their development in the two forms, as do also the blood-vessels.

Concerning the early development of the blood-vessels, there are considerable differences even between allied species of frogs. In *Rana esculenta* Maurer finds that there is at first in each branchial arch a single vessel or aortic arch, running directly from the heart to the aorta: from the cardiac end of this aortic arch a vessel grows out into the gill as the afferent branchial vessel, the original aortic arch losing its connection with the heart, and becoming the efferent branchial vessel. Afferent and efferent branchial vessels become connected by capillaries in the gill, and the course of the circulation, so long as gill-breathing is maintained, is from the heart through the truncus arteriosus to the afferent branchial vessel, then through the gill capillaries to the efferent branchial vessel, and then on to the aorta. When the pulmonary circulation is thoroughly established, the branchial circulation is cut off by the efferent vessel reacquiring its connection with the heart, when the blood naturally takes the direct passage along it to the aorta, and so escapes the gill capillaries.

In *Rana temporaria* the mode of development is very different: the afferent and efferent vessels arise in each arch independently and almost simultaneously: the afferent vessel soon acquires connection with the heart; but, unlike *R. esculenta*, the efferent vessel has no connection with the heart until the gills are about to atrophy.

In other words, the continuous aortic arch, from heart to aorta, is present in *R. esculenta* prior to the development of the gills: it becomes interrupted while the gills are in functional use, but is re-established when these begin to atrophy. In *R. temporaria*, on the other hand, there is no continuous aortic arch until the gills begin to atrophy.

The difference is an important one, for it is a matter of considerable morphological interest to determine whether the continuous aortic arch is primitive for vertebrates: *i.e.* whether it existed prior to the development of gills. This point could be practically settled if we could decide which of the two frogs, *R. esculenta* and *R. temporaria*, has most correctly preserved its ancestral history in this respect.

About this there can be little doubt. The development of the vessels in the newts, a less modified group than the frogs, agrees with that of *R. esculenta*, and interesting confirmation is afforded by a single aberrant specimen of *R. temporaria*, in which Mr. Bles and myself found the vessels developing after the type of *R.*

[1] "Ergebnisse naturwissenschaftlicher Forschungen auf Ceylon," vol. ii. chap. i. pp. 24-38.

esculenta, i.e. in which a complete aortic arch was present before the gills were formed.

We are therefore justified in concluding that as regards the development of the branchial blood-vessels, *R. esculenta* has retained a primitive ancestral character which is lost in *R. temporaria*, and it is interesting to note that were our knowledge of the development of amphibians confined to the common frog, the most likely form to be studied, we should, in all probability, have been led to wrong conclusions concerning the ancestral condition of the blood-vessels in a point of considerable importance.

A matter which at present is attracting much attention is the question of degeneration.

Natural selection, though consistent with and capable of leading to steady upward progress and improvement, by no means involves such progress as a necessary consequence. All it says is that those animals will, in each generation, have the best chance of survival which are most in harmony with their environment, and such animals will not necessarily be those which are ideally the best or most perfect.

If you go into a shop to purchase an umbrella, the one you select is by no means necessarily that which most nearly approaches ideal perfection, but the one which best hits off the mean between your idea of what an umbrella should be and the amount of money you are prepared to give for it: the one, in fact, that is on the whole best suited to the circumstances of the case, or the environment for the time being. It might well happen that you had a violent antipathy to a crooked handle, or else were determined to have a catch of a particular kind to secure the ribs, and this might lead to the selection, *i.e.* the survival, of an article that in other and even in more important respects was manifestly inferior to the average.

So it is also with animals: the survival of a form that is ideally inferior is very possible. To animals living in profound darkness the possession of eyes is of no advantage, and forms devoid of eyes would not merely lose nothing thereby, but would actually gain, inasmuch as they would escape the dangers that might arise from injury to a delicate and complicated organ. In extreme cases, as in animals leading a parasitic existence, the conditions of life may be such as to render locomotor, digestive, sensory, and other organs entirely useless; and in such cases those forms will be best in harmony with their surroundings which avoid the waste of energy resulting from the formation and maintenance of these organs.

Animals which have in this way fallen from the high estate of their forefathers, which have lost organs or systems which their progenitors possessed, are commonly called degenerate. The principle of degeneration, recognized by Darwin as a possible, and, under certain conditions, a necessary consequence of his theory of natural selection, has been since advocated strongly by Dohrn, and later by Lankester in an evening discourse delivered before the Association at the Sheffield meeting in 1879. Both Dohrn and Lankester suggested that degeneration occurred much more widely than was generally recognized.

In animals which are parasitic when adult, but free-swimming in their early stages, as in the case of the Rhizocephala, whose life-history was so admirably worked out by Fritz Müller, degeneration is clear enough: so also is it in the case of the solitary Ascidians, in which the larva is a free-swimming animal with a notochord, an elongated tubular nervous system, and sense organs, while the adult is fixed, devoid of the swimming tail, with no notochord, and with a greatly reduced nervous system and aborted sense organs.

In such cases the animal, when adult, is, as regards the totality of its organization, at a distinctly lower morphological level, is less highly differentiated than it is when young, and during individual development there is actual retrograde development of important systems and organs.

About such cases there is no doubt; but we are asked to extend the idea of degeneration much more widely. It is urged that we ought not to demand direct embryological evidence before accepting a group as degenerate. We are reminded of the tendency to abbreviation or to complete omission of ancestral stages of which we have quoted examples above; and it is suggested that if such larval stages were omitted in all the members of a group we should have no direct evidence of degeneration in a group that might really be in an extremely degenerate condition.

Supposing, for instance, the free larval stages of the solitary Ascidians were suppressed, say through the acquisition of food yolk, then it is urged that the degenerate condition of the group might easily escape detection. The supposition is by no means extravagant; food yolk varies greatly in amount in allied animals, and cases like Hylodes, or amongst Ascidians Pyrosoma, show how readily a mere increase in the amount of food yolk in the egg may lead to the omission of important ancestral stages.

The question then arises whether it is not possible, or even probable, that animals which now show no indication of degeneration in their development are in reality highly degenerate, and whether it is not legitimate to suppose such degeneration to have occurred in the case of animals whose affinities are obscure or difficult to determine.

It is more especially with regard to the lower vertebrates that this argument has been employed; and at the present day, zoologists of authority, relying on it, do not hesitate to speak of such forms as Amphioxus and the Cyclostomes as degenerate animals, as wolves in sheep's clothing, animals whose simplicity is acquired and deceptive rather than real and ancestral.

I cannot but think that cases such as these should be regarded with some jealousy; there is at present a tendency to invoke degeneration rather freely as a talisman to extricate us from morphological difficulties; and an inclination to accept such suggestions, at any rate provisionally, without requiring satisfactory evidence in their support.

Degeneration of which there is direct embryological evidence stands on a very different footing from suspected degeneration, for which no direct evidence is forthcoming; and in the latter case the burden of proof undoubtedly rests with those who assume its existence.

The alleged instances among the lower vertebrates must be regarded particularly closely, because in their case the suggestion of degeneration is admittedly put forward as a means of escape from difficulties arising through theoretical views concerning the relation between vertebrates and invertebrates.

Amphioxus itself, so far as I can see, shows in its development no sign of degeneration, except possibly with regard to the anterior gut diverticula, whose ultimate fate is not altogether clear. With regard to the earlier stages of development, concerning which, thanks to the patient investigations of Kowalevsky and Hatschek, our knowledge is precise, there is no animal known to us in which the sequence of events is simpler or more straightforward. Its various organs and systems are formed in what is recognized as a primitive manner; and the development of each is a steady upward progress towards the adult condition. Food yolk, the great cause of distortion in development, is almost absent, and there is not the slightest indication of the former possession of a larger quantity. Concerning the later stages our knowledge is incomplete, but so much as has been ascertained gives no support to the suggestion of general degeneration.

Our knowledge of the conditions leading to degeneration is undoubtedly incomplete, but it must be noticed that the conditions usually associated with degeneration do not occur. Amphioxus is not parasitic, is not attached when adult, and shows no evidence of having formerly possessed food yolk in quantity sufficient to have led to the omission of important ancestral stages. Its small size as compared with other vertebrates is one of the very few points that can be referred to as possibly indicating degeneration, and will be considered more fully at a later point in my address.

A consideration of much less importance, but deserving of mention, is that in its mode of life Amphioxus not merely differs as already noticed from those groups of animals which we know to be degenerate, but agrees with some, at any rate, of those which there is reason to regard as primitive or persistent types. Amphioxus, like Balanoglossus, Lingula, Dentalium, and Limulus, is marine, and occurs in shallow water, usually with a sandy bottom, and, like the three smaller of these genera, it lives habitually buried almost completely in the sand, into which it burrows with great rapidity.

I do not wish to speak dogmatically. I merely wish to protest against a too ready assumption of degeneration; and to repeat that, so far as I can see, Amphioxus has not yet, either in its development, in its structure, or in its habits, been shown to present characters that suggest, still less that prove, the occurrence in it of general or extensive degeneration.

In a sense, all the higher animals are degenerate; that is,

they can be shown to possess certain organs in a less highly developed condition than their ancestors, or even in a rudimentary state.

Thus a crab as compared with a lobster is degenerate in the matter of its tail, a horse as compared with Hipparion in regard to its outer toes; but it is neither customary nor advisable to speak of a crab as a degenerate animal compared to a lobster; to do so would be misleading. An animal should only be spoken of as degenerate when the retrograde development is well marked, and has affected not one or two organs only, but the totality of its organization.

It is impossible to draw a sharp line in such cases, and to limit precisely the use of the term degeneration. It must be borne in mind that no animal is at the top of the tree in all respects. Man himself is primitive as regards the number of his toes, and degenerate in respect to his ear muscles; and between two animals even of the same group it may be impossible to decide which of the two is to be called the higher and which the lower form.

Thus, to compare an oyster with a mussel. The oyster is more primitive than the mussel as regards the position of the ventricle of the heart and its relations to the alimentary canal; but is more modified in having but a single adductor muscle; and almost certainly degenerate in being devoid of a foot.

Care must also be taken to avoid speaking of an animal as degenerate in regard to a particular organ merely because that organ is less fully developed than in allied animals. An organ is not degenerate unless its present possessor has it in a less perfect condition than its ancestors had.

A man is not degenerate in the matter of the length of his neck as compared with a giraffe, nor as compared with an elephant in respect of the size of his front teeth, for neither elephant nor giraffe enters into the pedigree of man. A man is, however, degenerate, whoever his ancestors may have been, in regard to his ear muscles; for he possesses these in a rudimentary and functionless condition, which can only be explained by descent from some better equipped progenitor.

Closely connected with the question of degeneration is that of the size of animals, and its bearing on their structure and development; a problem noticed by many writers, but which has perhaps not yet received the attention it merits.

If we are right in interpreting the eggs of Metazoa as representing the unicellular or protozoan stage in their ancestry, then the small size of the egg may be viewed as recapitulatory.

But the gradual increase in size of the embryo, and its growth up to the adult condition, can only be regarded as representing in a most general way, if at all, the actual or even the relative sizes of the intermediate ancestral stages of the pedigree.

It is quite true that animals belonging to the lower groups are, as a general rule, of smaller size than those of higher grade; and also that the giants are met with among the highest members of each division. Cephalopoda are the highest molluscs, and the largest cephalopods greatly exceed in size any other members of the group; decapods are at once the highest and the largest crustaceans; and whales, the hugest animals that exist, or, so far as we know, that ever have existed, belong to the highest group of all, the mammalia. It would be easy to quote exceptions, but the general rule obtains admittedly.

However, although there may be, and probably is, a general parallelism between the increase in size from the egg to the adult, and the historical increase in size during the passage from lower to higher forms; yet no one could maintain that the sizes of embryos represent at all correctly those of the ancestors; that, for instance, the earliest birds were animals the size of a chick embryo at a time when avian characters first declared themselves, or that the ancestral series in all cases presented a steady progression in respect of actual magnitude.

In the lower animals, *e.g.*, in Orbitolites, the actual size of the several ancestral stages is probably correctly recapitulated during the growth of the adult; and it is very possible that it is so also in such forms as the solitary sponges. In higher animals, except in the early stages of those forms which are practically devoid of food yolk, and which hatch as pelagic larvæ, this certainly does not obtain.

This is clear enough, but is worth pointing out, for if, as most certainly is the case, the embryos of animals are actually smaller than the ancestral forms they represent, it is possible that the smallness of the embryo may have had some influence on its organization, and be responsible for some of the modifications in the ancestral history; and more especially for the disappearance of ancestral organs in free-swimming larvæ.

In adult animals the relation between size and structure has been very clearly pointed out by Herbert Spencer. Increased size involves by itself increased complexity of structure; the determining consideration being that while the surface area of the body increases as the squares of the linear dimensions, the mass of the body increases as their cubes.

If, for example, we imagine two animals of similar shape and proportions, but of different size; for the sake of simplicity, we may suppose them to be spherical, and that the diameter of one is twice that of the other; then the larger one will have four times the extent of surface of the smaller, but eight times its mass or bulk: and it is quite possible that while the extent of surface, or skin, in the smaller animal might suffice for the necessary respiratory and excretory interchanges, it would be altogether insufficient in the larger animal, in which increased extent of surface must be provided by foldings of the skin, as in the form of gills.

To take an actual instance; Limapontia is a minute nudibranchiate, or sea-slug, about the sixth of an inch in length; it has a smooth body, totally devoid of respiratory processes, while forms allied to it, but of larger size, have their extent of surface increased by branching processes, which often take the form of specialized gills.

This is a peculiarly instructive case, because Limapontia in its early developmental stages possesses a large spirally-coiled shell, and shows other evidence of descent from forms with specialized breathing organs. We are certainly right in associating the absence of respiratory organs in the adult with the small size of the animal; and comparison with allied forms suggests very strongly that there has been in its pedigree an actual reduction of size, which has led to the degeneration of the respiratory organs.

This is an important conclusion: it is a well-known fact that the smaller members of a group are, as a rule, more simply organized than the larger members, especially with regard to their respiratory and circulatory systems; but if we are right in concluding that reduction in size may be an actual cause of simplification or degeneration in structure, then we must be on our guard against assuming hastily that these smaller and simpler animals are necessarily primitive in regard to the groups to which they belong. It is possible, for instance, that the simplification or even absence of respiratory organs seen in Pauropus, in the Thysanura, and in other small Tracheata, may be a secondary character, acquired through reduction of size.

An interesting illustration of the law discussed above is afforded by the brains of mammals; it has been noticed by many anatomists that the extent of convolution, or folding of the surface of the cerebral hemispheres in mammals, is related not to the degree of intelligence of the animal, but to its actual size, a beaver having an almost smooth brain and a cow a highly complicated one. Jelgersma, and, independently of him, Prof. Fitzgerald,[1] have explained this as due to the necessity of preserving the due proportion between the outer layer of grey matter or cortex, which is approximately uniform in thickness, and the central mass of white matter. But for the foldings of the surface the proportion of white matter to grey matter would be far higher in a large than in a small brain.

It must not be forgotten, on the other hand, that many zoologists hold the view, in favour of which the evidence is steadily increasing, that the primitive or ancestral members of each group were of small size. Thus Fürbringer remarks, with regard to birds, that on the whole small birds show more primitive and simpler conditions of structure than the larger members of the same group. He expresses the opinion that the first birds were probably smaller than Archæopteryx, and notes that reptiles and mammals also show in their earlier and smaller types more primitive features than do their larger descendants. Finally, Fürbringer concludes that "it is therefore the study of the smaller members within given groups of animals which promises the best results as to their phylogeny."

Again, one of the most striking points with regard to the pedigree of the horse, as agreed on by palæontologists, is the progressive reduction in size which we meet with as we pass backwards in time from stage to stage. The Pliocene Hipparion was smaller than the existing horse, in fact about the size of a

[1] Cf. NATURE, June 5, 1890, p. 125.

donkey; the Miocene Mesohippus about equalled a sheep; while Eohippus, from the Lower Eocene deposits, was no larger than a fox. Not only is there good reason for holding that, as a rule, larger animals are descended from ancestors of smaller size, but there is also much evidence to show that increase in size beyond certain limits is disadvantageous, and may lead to destruction rather than to survival. It has happened more than once in the history of the world, and in more than one group of animals, that gigantic stature has been attained immediately before extinction of the group—a final and tremendous effort to secure survival, but a despairing and unsuccessful one. The Ichthyosauri, Plesiosauri, and other extinct reptilian groups, the Moas, and the huge extinct Edentates, are well-known examples, to which before long will be added the elephants and the whales, and, it may be, ironclads as well.

The whole question of the influence of size is of the greatest possible interest and importance, and it is greatly to be hoped that it will not be permitted to remain in its present uncertain and unsatisfactory condition.

It may be suggested that Amphioxus is an animal which has undergone reduction in size, and that its structural simplicity may, like that of Limapontia, be due, in part at least, to this reduction. Such evidence as we have tells against this suggestion; the first system to undergo degeneration in consequence of a reduction in size is the respiratory, and the respiratory organs of Amphioxus, though very simple, are also, for a vertebrate, unusually extensive.

We have now considered the more important of the influences which are recognized as affecting developmental history in such a way as to render the recapitulation of ancestral stages less complete than it might otherwise be, which tend to prevent ontogeny from correctly repeating the phylogenetic history. It may at this point reasonably be asked whether there is any way of distinguishing the palingenetic history from the later cenogenetic modifications grafted on to it—any test by which we can determine whether a given larval character is or is not ancestral.

Most assuredly there is no one rule, no single test, that will apply in all cases; but there are certain considerations which will help us, and which should be kept in view.

A character that is of general occurrence among the members of a group, both high and low, may reasonably be regarded as having strong claims to ancestral rank; claims that are greatly strengthened if it occurs at corresponding developmental periods in all cases; and still more if it occurs equally in forms that hatch early as free larvæ, and in forms with large eggs, which develop directly into the adult. As examples of such characters may be cited the mode of formation and relations of the notochord, and of the gill clefts of vertebrates, which satisfy all the conditions mentioned.

Characters that are transitory in certain groups, but retained throughout life in allied groups, may, with tolerable certainty, be regarded as ancestral for the former: for instance, the symmetrical position of the eyes in young flat fish, the spiral shell of the young limpet, the superficial positions of the madreporite in Elasipodous Holothurians, or the suckerless condition of the ambulacral feet in many Echinoderms.

A more important consideration is that if the developmental changes are to be interpreted as a correct record of ancestral history, then the several stages must be possible ones, the history must be one that could actually have occurred, *i.e.* the several steps of the history as reconstructed must form a series, all the stages of which are practicable ones.

Natural selection explains the actual structure of a complex organ as having been acquired by the preservation of a series of stages, each a distinct, if slight, advance on the stage immediately preceding it—an advance so distinct as to confer on its possessor an appreciable advantage in the struggle for existence. It is not enough that the ultimate stage should be more advantageous than the initial or earlier condition, but each intermediate stage must also be a distinct advance. If, then, the development of an organ is strictly recapitulatory, it should present to us a series of stages, each of which is not merely functional, but a distinct advance on the stage immediately preceding it. Intermediate stages, *e.g.* the œsophagus of the tadpole, which are not and could not be functional, can form no part of an ancestral series—a consideration well expressed by Sedgwick[1] thus: "Any phylogenetic hypothesis which presents difficulties from a physiological standpoint must be regarded as very provisional indeed."

A good example of an embryological series fulfilling these conditions is afforded by the development of the eye in the higher Cephalopoda. The earliest stage consists in the depression of a slightly modified patch of skin; round the edge of the patch the epidermis becomes raised up as a rim; this gradually grows inwards from all sides, so that the depressed patch now forms a pit, communicating with the exterior through a small hole or mouth. By further growth the mouth of the pit becomes still more narrowed, and ultimately completely closed, so that the pit becomes converted into a closed sac or vesicle; at the point at which final closure occurs, formation of cuticle takes place, which projects as a small transparent drop into the cavity of the sac; by formation of concentric layers of cuticle, this drop becomes enlarged into the spherical transparent lens of the eye, and the development is completed by histological changes in the inner wall of the vesicle, which convert it into the retina, and by the formation of folds of skin around the eye, which become the iris and the eyelids respectively.

Each stage in this developmental history is a distinct advance, physiologically, on the preceding stage, and, furthermore, each stage is retained at the present day as the permanent condition of the eye in some member of the group Mollusca.

The earliest stage, in which the eye is merely a slightly depressed and slightly modified patch of skin, represents the simplest condition of the Molluscan eye, and is retained throughout life in Solen. The stage in which the eye is a pit, with widely open mouth, is retained in the limpet; it is a distinct advance on the former, as through the greater depression the sensory cells are less exposed to accidental injury.

The narrowing of the mouth of the pit in the next stage is a simple change, but a very important step forwards. Up to this point the eye has served to distinguish light from darkness, but the formation of an image has been impossible. Now, owing to the smallness of the aperture, and the pigmentation of the walls of the pit which accompanies the change, light from any one part of an object can only fall on one particular part of the inner wall of the pit or retina, and so an image, though a dim one, is formed. This type of eye is permanently retained in the Nautilus.

The closing of the mouth of the pit by a transparent membrane will not affect the optical properties of the eye, and will be a gain, as it will prevent the entrance of foreign bodies into the cavity of the eye.

The formation of the lens by deposit of cuticle is the next step. The gain here is increased distinctness and increased brightness of the image, for the lens will focus the rays of light more sharply on the retina, and will allow a greater quantity of light, a larger pencil of rays from each part of the object, to reach the corresponding part of the retina. The eye is now in the condition in which it remains throughout life in the snail and other gastropods. Finally the formation of the folds of skin known as iris and eyelids provides for the better protection of the eye, and is a clear advance on the somewhat clumsy method of withdrawal seen in the snail.

The development of the vertebrate liver is another good but simpler example. The most primitive form of the liver is that of Amphioxus, in which it is present as a simple saccular diverticulum of the intestinal canal, with its wall consisting of a single layer of cells, and with blood-vessels on its outer surface. The earliest stage in the formation of the liver in higher vertebrates—the frog, for instance—is practically identical with this. In the frog the next stage consists in folding of the wall of the sac, which increases the efficiency of the organ by increasing the extent of surface in contact with the blood-vessels. The adult condition is attained simply by a continuance of this process; the foldings of the wall becoming more and more complicated, but the essential structure remaining the same—a single layer of epithelial cells in contact on one side with blood-vessels, and bounding on the other directly or indirectly the cavity of the alimentary canal.

It is not always possible to point out the particular advantage gained at each step even when a complete developmental series is known to us, but in such cases, as, for instance, in Orbitolites, our difficulties arise chiefly from ignorance of the particular conditions that confer advantage in the struggle for existence in the case of the forms we are dealing with.

[1] "On the Early Development of the Anterior Part of the Wolffian Duct and Body in the Chick" (*Quarterly Journal of Microscopical Science*, vol. xxi., 1881, p. 456).

The early larval stages in the development of animals, and more especially those that are marine and pelagic in habit, have naturally attracted much attention, since in the absence, probably inevitable, of satisfactory palæontological evidence, they afford us the sole available clue to the determination of the mutual relations of the large groups of animals, or of the points at which these diverged from one another.

In attempting to interpret these early ontogenetic stages as actual ancestral forms, beyond which development at one time did not proceed, we must keep clearly in view the various disturbing causes which tend to falsify the ancestral record, such as the influence of food yolk, or of habitat, and the tendency of diminution in size to give rise to simplification of structure, a point of importance if it be granted that these free larvæ are of smaller size than the ancestral forms to which they correspond.

If, on the other hand, in spite of these powerful modifying causes, we do find a particular larval form occurring widely and in groups not very closely akin, then we certainty are justified in attaching great importance to it, and in regarding it as having strong claims to be accepted as ancestral for these groups.

Concerning these larval forms, and their possible ancestral significance, our knowledge has made no great advance since the publication of Balfour's memorable chapter on this subject; and I propose merely to allude briefly to a few of the more striking instances.

The earliest, the most widely spread, and the most famous of larval forms is the gastrula, which occurs in a simple or in a modified form in some members of each of the large animal groups. It is generally admitted that its significance is the same in all cases, and the evidence is very strong in favour of regarding it as a stage ancestral for all Metazoa. The difficulty arising from its varying mode of development in different forms is, however, still unsolved, and embryologists are not yet agreed whether the invaginate or delaminate form is the more primitive. In favour of the former is its much wider occurrence; in favour of the latter the fact that it is easy to picture a series of stages leading gradually from a unicellular protozoon to a blastula, a diblastula, and ultimately a gastrula, each stage being a distinct advance, both morphological and physiological, on the preceding stage; while in the case of the invaginate gastrula it is not easy to imagine any advantage resulting from a flattening or slight pitting in of one part of the surface, sufficient to lead to its preservation and further development.

Of larval forms later than the gastrula, the most important by far is the Pilidium larva, from which it is possible, as Balfour has shown, that the slightly later Echinoderm larva, as well as the widely spread Trochosphere larva, may both be derived. Balfour concludes that the larval forms of all Cœlomata, excluding the Crustacea and vertebrates, may be derived from one common type, which is most nearly represented now by the Pilidium larva, and which "was an organism something like a Medusa, with a radial symmetry." The tendency of recent phylogenetic speculations is to accept this in full, and to regard as the ancestor of Turbellarians and of all higher forms, a jellyfish or ctenophoran, which, in place of swimming freely, has taken to crawling on the sea bottom.

Of the two groups excluded above, the Crustacea and the Vertebrata, the interest of the former centres in the much discussed problem of the significance of the Nauplius larva. There is now a fairly general agreement that the primitive Crustacea were types akin to the phyllopods, *i.e.* forms with elongated and many-segmented bodies, and a large number of pairs of similar appendages. If this is correct, then the explanation of the Nauplius stage must be afforded by the phyllopods themselves, and it is no use looking beyond this group for it. A Nauplius larva occurs in other Crustacea merely because they have inherited from their phyllopod ancestors the tendency to develop such a stage, and it is quite legitimate to hold that higher crustaceans are descended from phyllopods, and that the Nauplius represents in more or less modified form an earlier ancestor of the phyllopods themselves.

As to the Nauplius itself, the first thing to note is that, though an early larval form, it cannot be a very primitive form, for it is already an unmistakable crustacean; the absence of cilia, the formation of a cuticular investment, the presence of jointed schizopodous limbs, together with other anatomical characters, proving this point conclusively. It follows, therefore, either that the earlier and more primitive stages are entirely omitted in the development of Crustacea, or else that the Nauplius represents such an early ancestral stage, with crustacean characters, which properly belong to a later stage, thrown back upon it and precociously developed.

The latter explanation is the one usually adopted; but before the question can be finally decided, more accurate observations than we at present possess are needed concerning the stages intermediate between the egg and the Nauplius.

The absence of a heart in the Nauplius may reasonably be associated with the small size of the larva.

Concerning the larval forms of vertebrates, it is only in Amphioxus and the Ascidians that the earliest larval stages are free-living, independent animals. In both groups the most characteristic larval stage is that in which a notochord is present, and a neural tube, open in front, and communicating behind through a neurenteric canal with the digestive cavity, which has no other opening to the exterior. This is a very early stage, both in Amphioxus and Ascidians; but, so far as we know, it cannot be compared with any invertebrate larva. It is customary, in discussions on the affinities of vertebrates, to absolutely ignore the vertebrate larval forms, and to assume that their peculiarities are due to precocious development of vertebrate characteristics. It may turn out that this view of the matter is correct; but it has certainly not yet been proved to be so, and the development of both Amphioxus and Ascidians is so direct and straightforward that evidence of some kind may reasonably be required before accepting the doctrine that this development is entirely deceptive with regard to the ancestry of vertebrates.

Zoologists have not quite made up their minds what to do with Amphioxus: apparently the most guileless of creatures, many view it with the utmost suspicion, and not merely refuse to accept its mute protestations of innocence, but regard and speak of it as the most artful of deceivers. Few questions at the present day are in greater need of authoritative settlement.

That ontogeny really is a repetition of phylogeny must, I think, be admitted, in spite of the numerous and various ways in which the ancestral history may be distorted during actual development.

Before leaving the subject, it is worth while inquiring whether any explanation can be found of recapitulation. A complete answer can certainly not be given at present, but a partial one may, perhaps, be obtained.

Darwin himself suggested that the clue might be found in the consideration that at whatever age a variation first appears in the parent, it tends to reappear at a corresponding age in the offspring; but this must be regarded rather as a statement of the fundamental fact of embryology than as an explanation of it.

It is probably safe to assume that animals would not recapitulate unless they were compelled to do so: that there must be some constraining influence at work, forcing them to repeat more or less closely the ancestral stages. It is impossible, for instance, to conceive what advantage it can be to a reptilian or mammalian embryo to develop gill-clefts which are never used, and which disappear at a slightly later stage, or how it can benefit a whale, that in its embryonic condition it should possess teeth which never cut the gum, and which are lost before birth.

Moreover, the history of development in different animals or groups of animals, offers to us, as we have seen, a series of ingenious, determined, varied, but more or less unsuccessful efforts to escape from the necessity of recapitulating, and to substitute for the ancestral process a more direct method.

A further consideration of importance is that recapitulation is not seen in all forms of development, but only in sexual development, or, at least, only in development from the egg. In the several forms of asexual development, of which budding is the most frequent and most familiar, there is no repetition of ancestral phases; neither is there in cases of regeneration of lost parts, such as the tentacle of a snail, the arm of a starfish, or the tail of a lizard; in such regeneration it is not a larval tentacle, or arm, or tail, that is produced, but an adult one.

The most striking point about the development of the higher animals is that they all alike commence as eggs. Looking more closely at the egg and the conditions of its development, two facts impress us as of special importance: first, the egg is a single cell, and therefore represents morphologically the Protozoan, or earliest ancestral phase; secondly, the egg, before it can develop, must be fertilized by a spermatozoon, just as the stimulus of fertilization by the pollen-grain is necessary before the ovum of a plant will commence to develop into the plant-embryo.

The advantage of cross-fertilization in increasing the vigour of the offspring is well known, and in plants devices of the most varied and even extraordinary kind are adopted to ensure that such cross-fertilization occurs. The essence of the act of cross-fertilization, which is already established among Protozoa, consists in combination of the nuclei of two cells, male and female, derived from different individuals. The nature of the process is of such a kind that two individual cells are alone concerned in it; and it may, I think, be reasonably argued that the reason why animals commence their existence as eggs, *i.e.* as single cells, is because it is in this way only that the advantage of cross-fertilization can be secured, an advantage admittedly of the greatest importance, and to secure which natural selection would operate powerfully.

The occurrence of parthenogenesis, either occasionally or normally, in certain groups is not, I think, a serious objection to this view. There are very strong reasons for holding that parthenogenetic development is a modified form, derived from the sexual method. Moreover, the view advanced above does not require that cross-fertilization should be essential to individual development, but merely that it should be in the highest degree advantageous to the species, and hence leaves room for the occurrence, exceptionally, of parthenogenetic development.

If it be objected that this is laying too much stress on sexual reproduction, and on the advantage of cross-fertilization, then it may be pointed out in reply that sexual reproduction is the characteristic and essential mode of multiplication among Metazoa: that it occurs in all Metazoa, and that when asexual reproduction, as by budding, &c., occurs, this merely alternates with the sexual process which, sooner or later, becomes essential.

If the fundamental importance of sexual reproduction to the welfare of the species be granted, and if it be further admitted that Metazoa are descended from Protozoa, then we see that there is really a constraining force of a most powerful nature compelling every animal to commence its life-history in the unicellular condition, the only condition in which the advantage of cross-fertilization can be obtained; *i.e.* constraining every animal to begin its development at its earliest ancestral stage, at the very bottom of its genealogical tree.

On this view the actual development of any animal is strictly limited at both ends: it must commence as an egg, and it must end in the likeness of the parent. The problem of recapitulation becomes thereby greatly narrowed; all that remains being to explain why the intermediate stages in the actual development should repeat the intermediate stages of the ancestral history.

Although narrowed in this way, the problem still remains one of extreme difficulty.

It is a consequence of the theory of natural selection that identity of structure involves community of descent: a given result can only be arrived at through a given sequence of events: the same morphological goal cannot be reached by two independent paths. A negro and a white man have had common ancestors in the past; and it is through the long-continued action of selection and environment that the two types have been gradually evolved. You cannot turn a white man into a negro merely by sending him to live in Africa: to create a negro the whole ancestral history would have to be repeated; and it may be that it is for the same reason that the embryo must repeat or recapitulate its ancestral history in order to reach the adult goal.

I am not sure that we can at present get much further; but the above considerations give opportunity for brief notice of what is perhaps the most noteworthy of recent embryological papers, Kleinenberg's remarkable monograph on Lopadorhynchus.

Kleinenberg directs special attention to what is known to evolutionists as the difficulty with regard to the origin of new organs, which is to the effect that although natural selection is competent to account for any amount of modification in an organ after it has attained a certain size, and become of functional importance, yet that it cannot account for the earlier stages in the formation of an organ before it has become large enough or sufficiently developed to be of real use. The difficulty is a serious one: it is carefully considered by Mr. Darwin, and met completely in certain cases; but, as Kleinenberg correctly states, no general explanation has been offered with regard to such instances.

As such general explanation Kleinenberg proposes his theory of the development of organs by substitution. He points out that any modification of an organ or tissue must involve modification, at least in functional activity, of other organs. He then continues by urging that one organ may replace or be substituted for another, the replacing organ being in no way derived morphologically from the replaced or preceding organ, but having a genetic relation to it of this kind:—that it can only arise in an organism so constituted, and is dependent on the prior existence of the replaced organ, which supplies the necessary stimulus for its formation.

As an example he takes the axial skeleton of vertebrates. The notochord, formed by change of function from the wall of the digestive canal, is the sole skeleton of the lowest vertebrates, and the earliest developmental phase in all the higher forms. The notochord gives rise directly to no other organ, but is gradually replaced by other and unlike structures by substitution. The notochord is an intermediate organ, and the cartilaginous skeleton which replaces it is only intelligible through the previous existence of the notochord; while, in its turn, the cartilaginous skeleton gives way, being replaced, through substitution, by the bony skeleton.

The successive phases in the evolution of weapons might be quoted as an illustration of Kleinenberg's theory. The bow and arrow is a better weapon than a stick or stone; it is used for the same purpose, and the importance or need for a better weapon led to the replacement of the sling by the bow; the bow does not arise by further development or increasing perfection of the sling; it is an entirely new weapon, towards the formation of which the older and more primitive weapons have acted as a stimulus, and which has replaced these latter by substitution, while the substitution at a later date of firearms for the bow and arrow is merely a further instance of the same principle.

It is too early yet to realize the full significance of Kleinenberg's most suggestive theory; but if it be really true that each historic stage in the evolution of an organ is necessary as a stimulus to the development of the next succeeding stage, then it becomes clear why animals are constrained to recapitulate. Kleinenberg suggests further that the extraordinary persistence in embryonic life of organs which are rudimentary and functionless in the adult may also be explained by his theory, the presence of such organs in the embryo being indispensable as a stimulus to the development of the permanent structures of the adult.

It would be easy to point out difficulties in the way of the theory. The omission of historic stages in the actual ontogenetic development, of which almost all groups of animals supply striking examples, is one of the most serious; for if these stages are necessary as stimuli for the succeeding stages, then their omission requires explanation; while, if such stimuli are not necessary, the theory would appear to need revision.

Such objections may, however, prove to be less serious than they appear at first sight; and in any case Kleinenberg's theory may be welcomed as an important and original contribution, which deserves—indeed demands—the fullest and most careful consideration from all morphologists, and which acquires special interest from the explanation which it offers of recapitulation as a mechanical process, through which alone is it possible for an embryo to attain the adult structure.

That recapitulation does actually occur, that the several stages in the development of an animal are inseparably linked with and determined by its ancestral history, must be accepted. "To take any other view is to admit that the structure of animals and the history of their development form a mere snare to entrap our judgment."

Embryology, however, is not to be regarded as a master-key that is to open the gates of knowledge and remove all obstacles from our path without further trouble on our part; it is rather to be viewed and treated as a delicate and complicated instrument, the proper handling of which requires the utmost nicety of balance and adjustment, and which, unless employed with the greatest skill and judgment, may yield false instead of true results.

Embryology is indeed a most powerful and efficient aid, but it will not, and cannot, provide us with an immediate or complete answer to the great riddle of life. Complications, distortions, innumerable and bewildering, confront us at every step, and the progress of knowledge has so far served rather to increase the number and magnitude of these pitfalls than to teach us how to avoid them.

Still, there is no cause for despair—far from it; if our difficulties are increasing, so also are our means of grappling with them; if the goal appears harder to reach than we thought for, on the other hand its position is far better defined, and the means of approach, the lines of attack, are more clearly recognized.

One thing above all is apparent, that embryologists must not work single-handed, and must not be satisfied with an acquaintance, however exact, with animals from the side of development only; for embryos have this in common with maps, that too close and too exclusive a study of them is apt to disturb a man's reasoning power.

Embryology is a means, not an end. Our ambition is to explain in what manner and by what stages the present structure of animals has been attained. Towards this embryology affords most potent aid; but the eloquent protest of the great anatomist of Heidelberg must be laid to heart, and it must not be forgotten that it is through comparative anatomy that its power to help is derived.

What would it profit us, as Gegenbaur justly asks, to know that the higher vertebrates when embryos have slits in their throats, unless through comparative anatomy we were acquainted with forms now existing in which these slits are structures essential to existence? Anatomy defines the goal, tells us of the things that have to be explained; embryology offers a means, otherwise denied to us, of attaining it.

Comparative anatomy and palæontology must be studied most earnestly by those who would turn the lessons of embryology to best account, and it must never be forgotten that it is to men like Johannes Müller, Stannius, Cuvier, and John Hunter, the men to whom our exact knowledge of comparative anatomy is due, that we owe also the possibility of a science of embryology.

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY LIEUTENANT-COLONEL SIR R. LAMBERT PLAYFAIR, K.C.M.G., H.M. CONSUL-GENERAL IN ALGERIA, PRESIDENT OF THE SECTION.

The Mediterranean, Physical and Historical.

WHEN the unexpected honour was proposed to me of presiding over your deliberations, I felt some embarrassment as to the subject of my address. Geography as a science and the necessity of encouraging a more systematic study of it, had been treated in an exhaustive manner during previous meetings. The splendid discoveries of Stanley and the prolonged experiences of Emin have been amply illustrated by the personal narrative of the former. The progress of geography during the past year has been fully detailed in the annual address of the President of the Royal Geographical Society in June last; so that it would be a vain and presumptuous endeavour for me to compress these subjects into the limits of an opening address. Closely connected with them are the magnificent experiments for opening out Africa which are being made by our merchant princes, amongst whom the name of Sir William Mackinnon stands pre-eminent, and by our missionary societies of various churches, all acting cordially in unison, and sinking, in the dark continent, the differences and heartburnings which divide Christianity at home; I have thought it better, however, not to discuss matters so closely connected with political questions which have not yet passed into the realm of history.

In my perplexity I applied for the advice of one of the most experienced geographers of our Society, whose reply brought comfort to my mind. He reminded me that it was generally the custom for Presidents of Sections to select subjects with which they were best acquainted, and added: "What more instructive and captivating subject could be wished than THE MEDITERRANEAN, PHYSICAL AND HISTORICAL?"

For nearly a quarter of a century I have held an official position in Algeria, and it has been my constant delight to make myself acquainted with the islands and shores of the Mediterranean, in the hope of being able to facilitate the travels of my countrymen in that beautiful part of the world.

I cannot pretend to throw much new light on the subject, and I have written so often about it already that what I have to say may strike you as a twice-told tale: nevertheless, if you will permit me to descend from the elevated platform occupied by more learned predecessors, I should like to speak to you in a familiar manner of this "great sea," as it is called in sacred Scripture, the *Mare Internum* of the ancients, "our sea," *Mare nostrum* of Pomponius Mela.

Its shores include about three million square miles of the richest country on the earth's surface, enjoying a climate where the extremes of temperature are unknown, and with every variety of scenery, but chiefly consisting of mountains and elevated plateaux. It is a well-defined region of many parts, all intimately connected with each other by their geographical character, their geological formation, their flora, fauna, and the physiognomy of the people who inhabit them. To this general statement there are two exceptions—namely, Palestine, which belongs rather to the tropical countries lying to the east of it, and so may be dismissed from our subject; and the Sahara, which stretches to the south of the Atlantic region—or region of the Atlas—but approaches the sea at the Syrtis, and again to the eastward of the Cyrenaica, and in which Egypt is merely a long oasis on either side of the Nile.

The Mediterranean region is the emblem of fertility and the cradle of civilization, while the Sahara—Egypt, of course, excepted—is the traditional panther's skin of sand, dotted here and there with oases, but always representing sterility and barbarism. The sea is in no sense, save a political one, the limit between them; it is a mere gulf, which, now bridged by steam, rather unites than separates the two shores. Civilization never could have existed if this inland sea had not formed the junction between the three surrounding continents, rendering the coasts of each easily accessible, whilst modifying the climate of its shores.

The Atlas range is a mere continuation of the south of Europe. It is a long strip of mountain land, about 200 miles broad, covered with splendid forests, fertile valleys, and in some places arid steppes, stretching eastward from the ocean to which it has given its name. The highest point is in Morocco, forming a pendant to the Sierra Nevada of Spain; thence it runs, gradually decreasing in height, through Algeria and Tunisia, it becomes interrupted in Tripoli, and it ends in the beautiful green hills of the Cyrenaica, which must not be confounded with the oases of the Sahara, but is an island detached from the eastern spurs of the Atlas, in the ocean of the desert.

In the eastern part the flora and fauna do not essentially differ from those of Italy; in the west they resemble those of Spain; one of the noblest of the Atlantic conifers, the *Abies pinsapo*, is found also in the Iberian peninsula and nowhere else in the world, and the valuable alfa grass or esparto (*Stipa tenacissima*), from which a great part of our paper is now made, forms one of the principal articles of export from Spain, Portugal, Morocco, Algeria, Tunisia, and Tripoli. On both sides of the sea the former plant is found on the highest and most inaccessible mountains, amongst snows which last during the greater part of the year, and the latter from the sea-level to an altitude of 5000 feet, but in places where the heat and drought would kill any other plant, and in undulating land where water cannot lodge.

Of the 3000 plants found in Algeria by far the greater number are natives of Southern Europe, and less than 100 are peculiar to the Sahara. The *macchie* or maquis of Algeria in no way differs from that of Corsica, Sardinia, and other places; it consists of lentisk, arbutus, myrtle, cistus, tree-heath, and other Mediterranean shrubs. If we take the commonest plant found on the southern shores of the Mediterranean, the dwarf palm (*Chamærops humilis*), we see at once how intimately connected is the whole Mediterranean region, with the exception of the localities I have before indicated. This palm still grows spontaneously in the south of Spain, and in some parts of Provence, in Corsica, Sardinia, and the Tuscan Archipelago, in Calabria and the Ionian Islands, on the continent of Greece, and in several of the islands in the Levant, and it has only disappeared from other countries as the land has been brought under regular cultivation. On the other hand, it occurs neither in Palestine, Egypt, nor in the Sahara.

The presence of European birds may not prove much, but there are mammalia, fish, reptiles, and insects common to both sides of the Mediterranean. Some of the larger animals, such as the lion, panther, jackal, &c., have disappeared before the march of civilization in the one continent, but have lingered, owing to Mohammedan barbarism, in the other. There is abundant evidence of the former existence of these, and of the other large mammals which now characterize tropical Africa, in France, Germany, and Greece; it is probable that they only

migrated to their present habitat after the upheaval of the great sea which in Eocene times stretched from the Atlantic to the Indian Ocean, making Southern Africa an island continent like Australia. The original fauna of Africa, of which the lemur is the distinctive type, is still preserved in Madagascar, which then formed part of it.

The fish fauna is naturally the most conclusive evidence as to the true line of separation between Europe and Africa. We find the trout in the Atlantic region, and in all the snow-fed rivers falling into the Mediterranean; in Spain, Italy, Dalmatia; it occurs in Mount Olympus, in rivers of Asia Minor, and even in the Lebanon, but nowhere in Palestine south of that range, in Egypt, or in the Sahara. This fresh-water salmonoid is not exactly the same in all these localities, but is subject to considerable variation, sometimes amounting to specific distinction. Nevertheless, it is a European type found in the Atlas, and it is not till we advance into the Sahara, at Tuggurt, that we come to a purely African form in the Chromidæ, which have a wide geographical distribution, being found everywhere between that place, the Nile and Mozambique.

The presence of newts, tailed batrachians, in every country round the Mediterranean, except again in Palestine, Egypt, and the Sahara, is another example of the continuity of the Mediterranean fauna, even though the species are not the same throughout.

The Sahara is an immense zone of desert which commences on the shores of the Atlantic Ocean, between the Canaries and Cape de Verde, and traverses the whole of North Africa, Arabia, and Persia, as far as Central Asia. The Mediterranean portion of it may be said roughly to extend between the 15th and 30th degrees of north latitude.

This was popularly supposed to have been a vast inland sea in very recent times, but the theory was supported by geological facts wrongly interpreted. It has been abundantly proved by the researches of travellers and geologists that such a sea was neither the cause nor the origin of the Libyan Desert.

Rainless and sterile regions of this nature are not peculiar to North Africa, but occur in two belts which go round the world in either hemisphere, at about similar distances north and south of the equator. These correspond in locality to the great inland drainage areas from which no water can be discharged into the ocean, and which occupy about one-fifth of the total land surface of the globe.

The African Sahara is by no means a uniform plain, but forms several distinct basins containing a considerable extent of what may almost be called mountain land. The Hoggar Mountains in the centre of the Sahara are 7000 feet high, and are covered during three months with snow. The general average may be taken at 1500. The physical character of the region is very varied; in some places, such as at Tiout, Moghrar, Touat, and other oases in or bordering on Morocco, there are well-watered valleys, with fine scenery and almost European vegetation, where the fruits of the north flourish side by side with the palm tree. In others there are rivers like the Oued Guir, an affluent of the Niger, which the French soldiers, who saw it in 1870, compared to the Loire. Again, as in the bed of the Oued Rir, there is a subterranean river, which gives a sufficient supply of water to make a chain of rich and well-peopled oases equal in fertility to some of the finest portions of Algeria. The greater part of the Sahara, however, is hard and undulating, cut up by dry water-courses, such as the Igharghar, which descends to the Chott Melghigh, and almost entirely without animal or vegetable life.

About one-sixth of its extent consists of dunes of moving sand, a vast accumulation of detritus washed down from more northern and southern regions—perhaps during the glacial epoch—but with no indication of marine formation. These are difficult and even dangerous to traverse; but they are not entirely destitute of vegetation. Water is found at rare but well-known intervals, and there is an abundance of salsolaceous plants which serve as food for the camel. This sand is largely produced by wind action on the underlying rocks, and is not sterile in itself, it is only the want of water which makes it so. Wherever water does exist, or artesian wells are sunk, oases of great fertility never fail to follow.

Some parts of the Sahara are below the level of the sea, and here are formed what are called *chotts* or *sebkhas*, open depressions without any outlets, inundated by torrents from the southern slopes of the Atlas in winter and covered with a saline efflorescence in summer. This salt by no means proves the former existence of an inland sea; it is produced by the concentration of the natural salts, which exist in every variety of soil, washed down by winter rains, with which the unevaporated residue of water becomes saturated.

Sometimes the drainage, instead of flooding open spaces and forming chotts, finds its way through the permeable sand till it meets impermeable strata below it, thus forming vast subterranean reservoirs where the artesian sound daily works as great miracles as did Moses' rod of yore at Meribah. I have seen a column of water thrown up into the air equal to 1300 cubic metres per diem; a quantity sufficient to redeem 1800 acres of land from sterility and to irrigate 60,000 palm trees. This seems to be the true solution of the problem of an inland sea; a sea of verdure and fertility caused by the multiplication of artesian wells, which never fail to bring riches and prosperity in their train.

The climate of the Sahara is quite different from that of what I have called the Mediterranean region, where periodical rains divide the year into two seasons. Here, in many places, years elapse without a single shower; there is no refreshing dew at night, and the winds are robbed of their moisture by the immense continental extents over which they blow. There can be no doubt that it is to these meteorological, and not to geological, causes that the Sahara owes its existence.

Reclus divides the Mediterranean into two basins, which, in memory of their history, he calls the Phœnician and the Carthaginian, or the Greek and Roman seas, more generally known to us as the Eastern and Western Basins, separated by the island of Sicily.

If we examine the submarine map of the Mediterranean, we see that it must at one time have consisted of two enclosed or inland basins, like the Dead Sea. The western one is separated from the Atlantic by the Straits of Gibraltar, a shallow ridge, the deepest part of which is at its eastern extremity, averaging about 300 fathoms; while on the west, bounded by a line from Cape Spartel to Trafalgar, it varies from 50 to 200 fathoms. Fifty miles to the west of the Straits the bottom suddenly sinks down to the depths of the Atlantic, while to the east it descends to the general level of the Mediterranean, from 1000 to 2000 fathoms.

The Western is separated from the Eastern Basin by the isthmus which extends between Cape Bon in Tunisia and Sicily, known as the "Adventure Bank," on which there is not more than from 30 to 250 fathoms. The depth between Italy and Sicily is insignificant, and Malta is a continuation of the latter, being only separated from it by a shallow patch of from 50 to 100 fathoms; while to the east and west of this bank the depth of the sea is very great. These shallows cut off the two basins from all but superficial communication.

The configuration of the bottom shows that the whole of this strait was at one time continuous land, affording free communication for land animals between Africa and Europe. The palæontological evidence of this is quite conclusive. In the caves and fissures of Malta, amongst river detritus, are found three species of fossil elephants, a hippopotamus, a gigantic dormouse, and other animals which could never have lived in so small an island. In Sicily, remains of the existing elephant have been found, as well as the *Elephas antiquus*, and two species of hippopotamus, while nearly all these and many other animals of African type have been found in the Pliocene deposits and caverns of the Atlantic region.

The rapidity with which such a transformation might have occurred can be judged by the well-known instance of Graham's Shoal, between Sicily and the island of Pantellaria; this, owing to volcanic agency, actually rose above the water in 1832, and for a few weeks had an area of 3240 feet in circumference and a height of 107 feet.

The submersion of this isthmus no doubt occurred when the waters of the Atlantic were introduced through the Straits of Gibraltar. The rainfall over the entire area of the Mediterranean is certainly not more than 30 inches, while the evaporation is at least twice as great; therefore, were the Straits to be once more closed, and were there no other agency for making good this deficiency, the level of the Mediterranean would sink again till its basin became restricted to an area no larger than might be necessary to equalize the amount of evaporation and precipitation. Thus not only would the strait between Sicily and Africa be again laid dry, but the Adriatic and Ægean Seas also, and a great part of the Western Basin.

The entire area of the Mediterranean and Black Seas has been

estimated at upwards of a million square miles, and the volume of the rivers which are discharged into them at 226 cubic miles. All this and much more is evaporated annually. There are two constant currents passing through the Straits of Gibraltar, superimposed on each other; the upper and most copious one flows in from the Atlantic at a rate of nearly three miles an hour, or 140,000 cubic metres per second, and supplies the difference between the rainfall and evaporation, while the under-current of warmer water, which has undergone concentration by evaporation, is continually flowing out at about half the above rate of movement, getting rid of the excess of salinity; even thus, however, leaving the Mediterranean salter than any other part of the ocean except the Red Sea.

A similar phenomenon occurs at the eastern end, where the fresher water of the Black Sea flows as a surface current through the Dardanelles, and the salter water of the Mediterranean pours in below it.

The general temperature of the Mediterranean from a depth of fifty fathoms down to the bottom is almost constantly 56°, whatever may be its surface elevation. This is a great contrast to that of the Atlantic, which at a similar depth is at least 3° colder, and which at 1000 fathoms sinks to 40°.

This fact was of the greatest utility to Dr. Carpenter in connection with his investigations regarding currents through the Straits, enabling him to distinguish with precision between Atlantic and Mediterranean water.

For all practical purposes the Mediterranean may be accepted as being, what it is popularly supposed to be, a tideless sea, but it is not so in reality. In many places there is a distinct rise and fall, though this is more frequently due to winds and currents than to lunar attraction. At Venice there is a rise of from one to two feet in spring tides, according to the prevalence of winds up or down the Adriatic, but in that sea itself the tides are so weak that they can hardly be recognized, except during the prevalence of the Bora, our old friend *Boreas*, which generally raises a surcharge along the coast of Italy. In many straits and narrow arms of the sea there is a periodical flux and reflux, but the only place where tidal influence, properly so called, is unmistakably observed is in the Lesser Syrtis, or Gulf of Gabes; there the tide runs at the rate of two or three knots an hour, and the rise and fall varies from three to eight feet. It is most marked and regular at Djerba, the Homeric island of the Lotophagi; one must be careful in landing there in a boat, so as not to be left high and dry a mile or two from the shore. Perhaps the companions of Ulysses were caught by the receding tide, and it was not only a banquet of dates, the "honey-sweet fruit of the Lotus," or the potent wine which is made from it, which made them "forgetful of their homeward way."

The Gulf of Gabes naturally calls to mind the proposals which were made a few years ago for inundating the Sahara, and so restoring to the Atlantic region the insular condition which it is alleged to have had in prehistoric times. I will not allude to the English project for introducing the waters of the Atlantic from the west coast of Africa; that does not belong to my subject. The French scheme advocated by Commandant Roudaire, and supported by M. de Lesseps, was quite as visionary and impracticable.

To the south of Algeria and Tunis there exists a great depression stretching westward from the Gulf of Gabes to a distance of about 235 miles, in which are several *chotts* or salt lakes, sometimes only marshes, and in many places covered with a saline crust strong enough to bear the passage of camels. Commandant Roudaire proposed to cut through the isthmuses which separated the various chotts, and so prepare their basins to receive the waters of the Mediterranean. This done, he intended to introduce the sea by a canal, which should have a depth of one metre below low-water level.

This scheme was based on the assumption that the basin of the chotts had been an inland sea within historic times; that, little by little, owing to the difference between the quantity of water which entered and the amount of evaporation and absorption, this interior sea had disappeared, leaving the chotts as an evidence of the former condition of things; that, in fact, this was none other than the celebrated Lake Triton, the position of which has always been a puzzle to geographers.

This theory, however, is untenable; the isthmus of Gabes is not a mere sandbank; there is a band of rock between the sea and the basin of the chotts, through which the former never could have penetrated in modern times. It is much more probable that Lake Triton was the large bight between the island of Djerba and the mainland, on the shores of which are the ruins of the ancient city of Meninx, which, to judge by the abundance of Greek marble found there, must have carried on an important commerce with the Levant.

The scheme has now been entirely abandoned; nothing but the mania for cutting through isthmuses all over the world which followed the brilliant success achieved at Suez can explain its having been started at all. Of course, no mere mechanical operation is impossible in these days, but the mind refuses to realize the possibility of vessels circulating in a region which produces nothing, or that so small a sheet of water in the immensity of the Sahara could have any appreciable effect in modifying the climate of its shores.

The Eastern Basin is much more indented and cut up into separate seas than the Western one; it was therefore better adapted for the commencement of commerce and navigation its high mountains were landmarks for the unpractised sailor, and its numerous islands and harbours afforded shelter for his frail barque, and so facilitated communication between one point and another.

The advance of civilization naturally took place along the axis of this sea, Phœnicia, Greece, and Italy being successively the great nurseries of human knowledge and progress. Phœnicia had the glory of opening out the path of ancient commerce, for its position in the Levant gave it a natural command of the Mediterranean, and its people sought the profits of trade from every nation which had a seaboard on the three continents washed by this sea. Phœnicia was already a nation before the Jews entered the Promised Land, and when they did so they carried on inland traffic as middlemen to the Phœnicians. Many of the commercial centres on the shores of the Mediterranean were founded before Greece and Rome acquired importance in history. Homer refers to them as daring traders nearly a thousand years before the Christian era.

For many centuries the commerce of the world was limited to the Mediterranean, and when it extended in the direction of the East it was the merchants of the Adriatic, of Genoa, and of Pisa who brought the merchandise of India, at an enormous cost, to the Mediterranean by land, and who monopolized the carrying trade by sea. It was thus that the elephant trade of India, the caravan traffic through Babylon and Palmyra, as well as the Arab *kafilehs*, became united with the Occidental commerce of the Mediterranean.

As civilization and commerce extended westwards, mariners began to overcome their dread of the vast solitudes of the ocean beyond the Pillars of Hercules, and the discovery of America by Columbus, and the circumnavigation of Africa by the Portuguese, changed entirely the current of trade as well as increased its magnitude, and so relegated the Mediterranean, which had hitherto been the central sea of human intercourse, to a position of secondary importance.

Time will not permit me to enter into further details regarding the physical geography of this region, and its history is a subject so vast that a few episodes of it are all that I can possibly attempt. It is intimately connected with that of every other country in the world, and here were successively evolved all the great dramas of the past and some of the most important events of less distant date.

As I have already said, long before the rise of Greece and Rome its shores and islands were the seat of an advanced civilization. Phœnicia had sent out her pacific colonies to the remotest parts, and not insignificant vestiges of their handicraft still exist to excite our wonder and admiration. We have the megalithic temples of Malta sacred to the worship of Baal, the generative god, and Ashtoreth, the conceptive goddess, of the universe. The three thousand *nurhagi* of Sardinia, round towers of admirable masonry, intended probably for defence in case of sudden attack, and the so-called giant graves, were as great a mystery to classical authors as they are to us at the present day. Menorca has its *talayots*, tumuli somewhat analogous to, but of ruder construction than, the *nurhagi*, more than 200 groups of which exist in various parts of the island; with these are associated subordinate constructions intended for worship; altars composed of two immense monoliths, erected in the form of a T; sacred enclosures and megalithic habitations. One type of *talayot* is especially remarkable, of better masonry than the others, and exactly resembling inverted boats. One is tempted to believe that the Phœnicians had in view the grass habitations

or *mapalia* of the Numidians described by Sallust, and had endeavoured to reproduce them in stone: *Oblonga, incurvis lateribus tecta, quasi navium carinæ sunt.*

For a long time the Phœnicians had no rivals in navigation, but subsequently the Greeks—especially the Phocians—established colonies in the Western Mediterranean, in Spain, Corsica, Sardinia, Malta, and the south of France, through the means of which they propagated not only their commerce but their arts, literature, and ideas. They introduced many valuable plants, such as the olive, thereby modifying profoundly the agriculture of the countries in which they settled. They have even left traces of their blood, and it is no doubt to this that the women of Provence owe the classical beauty of their features.

But they were eclipsed by their successors; the empire of Alexander opened out a road to India, in which, indeed, the Phœnicians had preceded him, and introduced the produce of the East into the Mediterranean, while the Tyrian colony of Carthage became the capital of another vast empire, which, from its situation, midway between the Levant and the Atlantic Ocean, enabled it to command the Mediterranean traffic.

The Carthaginians at one time ruled over territory extending along the coast from Cyrene to Numidia, besides having a considerable influence over the interior of the continent, so that the name of Africa, given to their own dominions, was gradually applied to a whole quarter of the globe. The ruling passion with the Carthaginians was love of gain, not patriotism, and their wars were largely fought with mercenaries. It was the excellence of her civil constitution which, according to Aristotle, kept in cohesion for centuries her straggling possessions. A country feebly patriotic, which entrusts her defence to foreigners, has the seeds of inevitable decay, which ripened in her struggle with Rome, despite the warlike genius of Hamilcar and the devotion of the magnanimous Hannibal. The gloomy and cruel religion of Carthage, with its human sacrifices to Moloch and its worship of Baal under the name of Melkarth, led to a criminal code of Draconic severity and alienated it from surrounding nations. When the struggle with Rome began, Carthage had no friends. The first Punic War was a contest for the possession of Sicily, whose prosperity is even now attested by the splendour of its Hellenic monuments. When Sicily was lost by the Carthaginians, so also was the dominion of the sea, which hitherto had been uncontested. The second Punic War resulted in the utter prostration of Carthage and the loss of all her possessions out of Africa; and in 201 B.C., when this war was ended, 552 years after the foundation of the city, Rome was mistress of the world.

The destruction of Carthage after the third Punic War was a heavy blow to Mediterranean commerce. It was easy for Cato to utter his stern *Delenda est Carthago;* destruction is easy, but construction is vastly more difficult. Although Augustus in his might built a new Carthage near the site of the old city, he could never attract again the trade of the Mediterranean which had been diverted into other channels. Roman supremacy was unfavourable to the growth of commerce, because, though she allowed unrestricted trade throughout her vast empire, and greatly improved internal communications in the subjugated countries, Rome itself absorbed the greater part of the wealth, and did not produce any commodities in return for its immense consumption, therefore Mediterranean commerce did not thrive under the Roman rule. The conquest of Carthage, Greece, Egypt, and the East poured in riches to Rome, and dispensed for a time with the needs of productive industry, but formed no enduring basis of prosperity.

It is only in relation to the Mediterranean that I can refer to Roman history, but I must allude to the interesting episode in the life of Diocletian, who, after an anxious reign of twenty-one years in the eastern division of the empire, abdicated at Nicomedia and retired to his native province of Illyria. He spent the rest of his life in rural pleasures and horticulture at Salona, near which he built that splendid palace within the walls of which subsequently arose the modern city of Spalato. Nothing more interesting exists on the shores of the Mediterranean than this extraordinary edifice, perhaps the largest that ever arose at the bidding of a single man; not only vast and beautiful, but marking one of the most important epochs in the history of architecture.

Though now obstructed with a mass of narrow, tortuous streets, its salient features are distinctly visible. The great temple, probably the mausoleum of the founder, has become the cathedral, and after the Pantheon at Rome there is no finer specimen of a heathen temple turned into a Christian church. Strange it is that the tomb of him whose reign was marked by such unrelenting persecution of the Christians should have been accepted as the model of those baptisteries so commonly constructed in the following centuries.

Of Diocletian's Salona, one of the chief cities of the Roman world, but little now remains save traces of the long irregular wall; recent excavations have brought to light much that is interesting, but all of the Christian epoch, such as a large basilica which had been used as a necropolis, and a baptistery, one of those copied from the temple of Spalato, on the Mosaic pavement of which can still be read the text, *Sicut cervus desiderat fontem aquarum ita anima mea ad te Deus.*

The final partition of the Roman Empire took place in 365; forty years later the barbarians of the North began to invade Italy and the south of Europe; and in 429, Genseric, at the head of his Vandal hordes, crossed over into Africa from Andalusia, a province which still bears their name, devastating the country as far as the Cyrenaica. He subsequently annexed the Balearic Islands, Corsica and Sardinia, he ravaged the coasts of Italy and Sicily, and even of Greece and Illyria, but the most memorable of his exploits was the unresisted sack of Rome, whence he returned to Africa laden with treasure and bearing the Empress Eudoxia a captive in his train.

The degenerate emperors of the West were powerless to avenge this insult, but Byzantium, though at this time sinking to decay, did make a futile attempt to attack the Vandal monarch in his African stronghold. It was not, however, till 533, in the reign of Justinian, when the successors of Genseric had fallen into luxurious habits and had lost the rough valour of their ancestors, that Belisarius was able to break their power and take their last king a prisoner to Constantinople. The Vanda domination in Africa was destroyed, but that of the Byzantines was never thoroughly consolidated; it rested not on its own strength, but on the weakness of its enemies, and it was quite unable to cope with the next great wave of invasion which swept over the land, perhaps the most extraordinary event in the world's history, save only the introduction of Christianity.

In 647, twenty-seven years after the Hedjira of Mohammed, Abdulla ibn Saad started from Egypt for the conquest of Africa with an army of 40,000 men.

The expedition had two determining causes—the hope of plunder and the desire to promulgate the religion of El Islam. The sands and scorching heat of the desert, which had nearly proved fatal to the army of Cato, were no bar to the hardy Arabians and their enduring camels. The march to Tripoli was a fatiguing one, but it was successfully accomplished; the invaders did not exhaust their force in a vain effort to reduce its fortifications, but swept on over the Syrtic desert, and north to the province of Africa, where, near the splendid city of Suffetula, a great battle was fought between them and the army of the Exarch Gregorius, in which the Christians were signally defeated, their leader killed, and his daughter allotted to Ibn-ez-Zobair, who had slain her father.

Not only did the victorious Moslems overrun North Africa, but soon they had powerful fleets at sea which dominated the entire Mediterranean, and the emperors of the East had enough to do to protect their own capital.

Egypt, Syria, Spain, Provence, and the islands of the Mediterranean successively fell to their arms, and until they were checked at the Pyrenees by Charles Martel it seemed at one time as if the whole of Southern Europe would have been compelled to submit to the disciples of the new religion. Violent, implacable, and irresistible at the moment of conquest, the Arabs were not unjust or hard masters in countries which submitted to their conditions. Every endeavour was, of course, made to proselytize, but Christians were allowed to preserve their religion on payment of a tax, and even Popes were in the habit of entering into friendly relations with the invaders. The Church of St. Cyprian and St. Augustine, with its 500 Sees, was indeed expunged, but five centuries after the passage of the Mohammedan army from Egypt to the Atlantic a remnant of it still existed. It was not till the twelfth century that the religion and language of Rome became utterly extinguished.

The Arabs introduced a high state of civilization into the countries where they settled; their architecture is the wonder and admiration of the world at the present day; their irrigational

works in Spain have never been improved upon; they fostered literature and the arts of peace, and introduced a system of agriculture far superior to what existed before their arrival.

Commerce, discouraged by the Romans, was highly honoured by the Arabs, and during their rule the Mediterranean recovered the trade which it possessed in the time of the Phœnicians and Carthaginians; it penetrated into the Indian Archipelago and China; it travelled westward to the Niger, and to the east as far as Madagascar, and the great trade route of the Mediterranean was once more developed.

The power and prosperity of the Arabs culminated in the ninth century, when Sicily fell to their arms; it was not, however, very long before their empire began to be undermined by dissensions; the temporal and spiritual authority of the Ommiade Khalifs, which extended from Sind to Spain, and from the Oxus to Yemen, was overthrown by the Abbasides in the year 132 of the Hedjira, A.D. 750. Seven years later Spain detached itself from the Abbasside empire; a new Caliphate was established at Cordova, and hereditary monarchies began to spring up in other Mohammedan countries.

The Carlovingian empire gave an impulse to the maritime power of the south of Europe, and in the Adriatic the fleets of Venice and Ragusa monopolized the traffic of the Levant. The merchants of the latter noble little republic penetrated even to our own shores, and Shakespeare has made the Argosy or Ragusie a household word in our language.

During the eleventh century the Christian Powers were no longer content to resist the Mohammedans: they began to turn their arms against them. If the latter ravaged some of the fairest parts of Europe, the Christians began to take brilliant revenge.

The Mohammedans were driven out of Corsica, Sardinia, Sicily, and the Balearic Islands, but it was not till 1492 that they had finally to abandon Europe, after the conquest of Granada by Ferdinand and Isabella.

About the middle of the eleventh century an event took place which profoundly modified the condition of the Mohammedan world. The Caliph Mostansir let loose a horde of nomad Arabs, who, starting from Egypt, spread over the whole of North Africa, carrying destruction and blood wherever they passed, thus laying the foundation for the subsequent state of anarchy which rendered possible the interference of the Turks.

English commercial intercourse with the Mediterranean was not unknown even from the time of the Crusades, but it does not appear to have been carried on by means of our own vessels till the beginning of the sixteenth century. In 1522 it was so great that Henry VIII. appointed a Cretan merchant, Censio de Balthazari, to be "Master, governor, protector, and consul of all and singular the merchants and others his lieges and subjects within the port, island, and country of Crete or Candia." This is the very first English consul known to history, but the first of English birth was my own predecessor in office, Master John Tipton, who, after having acted at Algiers during several years in an unofficial character, probably elected by the merchants themselves to protect their interests, was duly appointed consul by Sir William Harebone, ambassador at Constantinople in 1585, and received just such an exequatur from the Porte as has been issued to every consul since by the Government of the country in which he resides.

Piracy has always been the scourge of the Mediterranean, but we are too apt to associate its horrors entirely with the Moors and Turks. The evil had existed from the earliest ages; even before the Roman conquest of Dalmatia the Illyrians were the general enemies of the Adriatic; Africa under the Vandal reign was a nest of the fiercest pirates; the Venetian chronicles are full of complaints of the ravages of the Corsairs of Ancona, and there is no other name but piracy for such acts of the Genoese as the unprovoked pillage of Tripoli by Andrea Doria in 1535. To form a just idea of the Corsairs of the past it is well to remember that commerce and piracy were often synonymous terms, even among the English, up to the reign of Elizabeth. Listen to the description given by the pious Cavendish of his commercial circumnavigation of the globe:—"It hath pleased Almighty God to suffer me to circumpass the whole globe of the world. . . . I navigated along the coast of Chili, Peru, and New Spain, where I made great spoils. All the villages and towns that ever I landed at I burned and spoiled, and had I not been discovered upon the coast I had taken a great quantity of treasure," and so he concludes, "The Lord be praised for all his mercies!"

Sir William Monson, when called upon by James I. to propose a scheme for an attack on Algiers, recommended that all the maritime Powers of Europe should contribute towards the expense, and participate in the gains by the sale of Moors and Turks as slaves.

After the discovery of America and the expulsion of the Moors from Spain, piracy developed to an extraordinary extent. The audacity of the Barbary corsairs seems incredible at the present day; they landed on the shores and islands of the Mediterranean, and even extended their ravages to Great Britain, carrying off all the inhabitants whom they could seize into the most wretched slavery. The most formidable of these piratical States was Algiers, a military oligarchy, consisting of a body of janissaries, recruited by adventurers from the Levant, the outcasts of the Mohammedan world, criminals and renegades from every nation in Europe. They elected their own ruler or Dey, who exercised despotic sway, tempered by frequent assassination; they oppressed without mercy the natives of the country, accumulated vast riches, had immense numbers of Christian slaves, and kept all Europe in a state bordering on subjection by the terror which they inspired. Nothing is sadder or more inexplicable than the shameful manner in which this state of things was accepted by civilized nations. Many futile attempts were made during successive centuries to humble their arrogance, but it only increased by every manifestation of the powerlessness of Europe to restrain it. It was reserved for our own countryman, Lord Exmouth, by his brilliant victory in 1816, for ever to put an end to piracy and Christian slavery in the Mediterranean. His work, however, was left incomplete, for though he destroyed the navy of the Algerines, and so rendered them powerless for evil on the seas, they were far from being humbled; they continued to slight their treaties and to subject even the agents of powerful nations to contumely and injustice. The French took the only means possible to destroy this nest of ruffians, by the almost unresisted occupation of Algiers and the deportation of its Turkish aristocracy.

They found the whole country in the possession of a hostile people, some of whom had never been subdued since the fall of the Roman Empire, and the world owes France no small debt of gratitude for having transformed what was a savage and almost uncultivated country into one of the richest as well as the most beautiful in the basin of the Mediterranean.

What has been accomplished in Algeria is being effected in Tunisia. The treaty of the Kasr-es-Saeed, which established a French Protectorate there, and the military occupation of the Regency, were about as high-handed and unjustifiable acts as are recorded in history; but there can be no possible doubt regarding the important work of civilization and improvement that has resulted from them. European courts of justice have been established all over the country; the exports and imports have increased from twenty-three to fifty-one millions of francs, the revenue from six to nineteen millions, without the imposition of a single new tax, and nearly half a million per annum is being spent on education.

Sooner or later the same thing must happen in the rest of North Africa, though at present international jealousies retard this desirable consummation. It seems hard to condemn such fair countries to continued barbarism, in the interest of tyrants who misgovern and oppress their people. The day cannot be far off when the whole southern shores of the Mediterranean will enjoy the same prosperity and civilization as the northern coast, and when the deserts, which are the result of misgovernment and neglect, will assume the fertility arising from security and industry, and will again blossom as the rose.

It cannot be said that any part of the Mediterranean basin is still unknown, if we except the empire of Morocco. But even that country has been traversed in almost every direction during the past twenty years, and its geography and natural history have been illustrated by men of the greatest eminence; such as Gerhard Rohlfs, Monsieur Tissot, Sir Joseph Hooker, the Vicomte de Foucauld, Joseph Thomson, and numerous other travellers. The least known portion, at least on the Mediterranean coast, is the Riff country, the inhospitality of whose inhabitants has given the word "ruffian" to the English language. Even that has been penetrated by De Foucauld disguised as a Jew, and the record of his exploration is one of the most brilliant contributions to the geography of the country which has hitherto been made.

Although, therefore, but little remains to be done in the way of actual exploration, there are many by-ways of travel com-

paratively little known to that class of the community with which I have so much sympathy, the ordinary British tourist. These flock every year in hundreds to Algeria and Tunis, but few of them visit the splendid Roman remains in the interior of those countries. The Cyrenaica is not so easily accessible, and I doubt whether any Englishmen have travelled in it since the exploration of Smith and Porcher in 1861.

Cyrene almost rivalled Carthage in commercial importance. The Hellenic ruins still existing bear witness to the splendour of its five great cities. It was the birthplace of many distinguished people, and amongst its hills and fountains were located some of the most interesting scenes in mythology, such as the Gardens of the Hesperides, and the "silent, dull, forgetful waters of Lethe."

This peninsula is only separated by a narrow strait from Greece, whence it was originally colonized. There, and indeed all over the eastern basin of the Mediterranean, are many little-trodden routes; but the subject is too extensive; I am reluctantly compelled to restrict my remarks to the western half.

The south of Italy is more frequently traversed and less travelled in than any part of that country. Of the thousands who yearly embark or disembark at Brindisi, few ever visit the Land of Manfred. Otranto is only known to them from the fanciful descriptions in Horace Walpole's romance. The general public in this country is quite ignorant of what is going on at Taranto, and of the great arsenal and dockyard which Italy is constructing in the Mare Piccolo, an inland sea containing more than 1000 acres of anchorage for the largest ironclads afloat, yet with an entrance so narrow that it is spanned by a revolving bridge. Even the Adriatic, though traversed daily by steamers of the Austrian Lloyd's Company, is not a highway of travel; yet where is it possible to find so many places of interest within the short space of a week's voyage, between Corfu and Trieste, as along the Dalmatian and Istrian shores, and among the islands that fringe the former, where it is difficult to realize that one is at sea at all, and not on some great inland lake?

There is the Bocche di Cattaro, a vast rent made by the Adriatic among the mountains, where the sea flows round their spurs in a series of canals, bays, and lakes of surpassing beauty. The city of Cattaro itself, the gateway of Montenegro, with its picturesque Venetian fortress, nestling at the foot of the black mountain, Ragusa, the Roman successor of the Hellenic Epidaurus, Queen of the Southern Adriatic, battling with the waves on her rock-bound peninsula, the one spot in all that sea which never submitted either to Venice or the Turk, and for centuries resisting the barbarians on every side, absolutely unique as a mediæval fortified town, and worthy to have given her name to the argosies she sent forth; Spalato, the grandest of Roman monuments; Lissa, colonized by Dionysius of Syracuse, and memorable to us as having been a British naval station from 1812 to 1814, while the French held Dalmatia; Zara, the capital, famous for its siege by the Crusaders, interesting from an ecclesiological point of view, and venerated as the last resting-place of St. Simeon, the prophet of the *Nunc dimittis;* Parenza, with its great basilica; Pola, with its noble harbour, whence Belisarius sailed forth, now the chief naval port of the Austrian Empire, with its Roman amphitheatre and graceful triumphal arches; besides many other places of almost equal interest. Still further west are Corsica, Sardinia, and the Balearic Islands, all easily accessible from the coasts of France, Italy, and Spain. Their ports are constantly visited by mail-steamers and private yachts, yet they are but little explored in the interior.

A physical and historical description of Corsica was then given. The address concluded as follows:—

I have endeavoured to sketch, necessarily in a very imperfect manner, the physical character and history of the Mediterranean, to show how the commerce of the world originated in a small maritime State at its eastern extremity; how it gradually advanced westward till it burst through the Straits of Gibraltar, and extended over seas and continents until then undreamt of, an event which deprived the Mediterranean of that commercial prosperity and greatness which for centuries had been limited to its narrow basin.

Once more this historic sea has become the highway of nations; the persistent energy and genius of two men have revolutionized navigation, opened out new and boundless fields for commerce; and it is hardly too much to say that if the Mediterranean is to be restored to its old position of importance; if the struggle for Africa is to result in its regeneration, as happened in the New World; if the dark places still remaining in the further East are to be civilized, it will be in a great measure due to Waghorn and Ferdinand de Lesseps, who developed the overland route and created the Suez Canal.

But the Mediterranean can only hope to retain its regenerated position in time of peace. Nothing is more certainly shown by past history than that war and conquest have changed the route of commerce in spite of favoured geographical positions. Babylon was conquered by Assyrians, Persians, Macedonians, and Romans, and though for a time her position on the Euphrates caused her to rise like a Phœnix from her ashes, successive conquests, combined with the luxury and effeminacy of her rulers, caused her to perish. Tyre, conquered by Nebuchadnezzar and Alexander, fell as completely as Babylon had done, and her trade passed to Alexandria. Ruined sites of commercial cities rarely again become emporia of commerce; Alexandria is an exception dependent on very exceptional circumstances.

The old route to the East was principally used by sailing-vessels, and was abandoned for the shorter and more economical one by the Suez Canal, which now enables a round voyage to be made in sixty days, which formerly required from six to eight months. This, however, can only remain open in time of peace. It is quite possible that in the event of war the old route by the Cape may be again used, to the detriment of traffic by the Mediterranean. Modern invention has greatly economized the use of coal; and steamers, by the use of duplex and triplex engines, can run with a comparatively small consumption of fuel, thus leaving a larger space for cargo. England, the great carrying Power of the world, may find it more advantageous to trust to her own strength and the security of the open seas than to run the gauntlet of the numerous strategical positions in the Mediterranean, such as Port Mahon, Bizerta, and Taranto, each of which is capable of affording impregnable shelter to a hostile fleet, and though the ultimate key to the Indian Ocean is in our own hands, our passage to it may be beset with a thousand dangers. There is no act of my career on which I look back with so much satisfaction as on the share I had in the occupation of Perim, one of the most important links in that chain of coaling stations which extends through the Mediterranean to the further East, and which is so necessary for the maintenance of our naval supremacy. It is a mere islet, it is true, a barren rock, but one surrounding a noble harbour, and so eminently in its right place that we cannot contemplate with equanimity the possibility of its being in any other hands than our own.

It is by no means certain whether exaggerated armaments are best suited for preserving peace or hastening a destructive war; the golden age of disarmament and international arbitration may not be near at hand, but it is even now talked of as a possibility.

Should the poet's prophecy or the patriot's dream be realized, and a universal peace indeed bless the world, then this sea of so many victories may long remain the harvest field of a commerce nobler than conquest.

NOTES.

THE Kew Herbarium has just been enriched by a set of the dried plants from the extensive collections made by Regel, Przewalski, Potanin, and other recent Russian travellers in Central and Eastern Asia. This valuable set numbers about 2600 species, including very many novelties, and it was presented to the Royal Gardens, Kew, through the good offices of Dr. A. E. von Regel, Director of the Imperial Botanic Garden at St. Petersburg, and Mr. C. J. Maximowicz, the Curator of the Herbarium in the same establishment.

A LABORATORY for plant-biology has been recently opened at Fontainebleau. It is under the direction of M. Bonnier, Professor of Botany at the Sorbonne in Paris, to whom application should be made by any contemplating research there.

DR. WILLIAM WAAGEN, F.G.S., formerly Palæontologist to the Geological Survey of India, and of late years Professor of Geology at Prague, has been appointed Professor of Palæontology to the University of Vienna, in succession to the late Dr. Neumayr.

IN a "Supplement to the Catalogue of Diurnal Accipitres in the Australian Museum at Sydney, N.S.W.," Dr. E. P. Ramsay

gives descriptions of many plumages of birds of prey not previously recorded. The nestlings described have been preserved for the Museum by Mr. K. H. Bennett, and include those of the rarest of the Australian accipitres. The colours of the soft parts have been most carefully noted, and are deemed in one instance (*Aquila morphnoides*, p. 7) to be worthy of a duplicate reproduction by Dr. Ramsay.

THE Rev. Dr. Norman has just returned from a dredging expedition in the Varanger Fiord and Sydvaranger. He has been absent nine weeks, and has brought home extensive collections in all branches of Marine Invertebrata. The fiords of Sydvaranger were found to possess a rich fauna, with depths descending to 120 fathoms. These fiords had never before been scientifically investigated, though Baron de Guerne took a few hauls of the dredge there in 1881 when on board the French vessel *Coligny* as a member of the Mission Scientifique en Laponie, and published a list of the Mollusca obtained.

DR. RAMSAY has also compiled a catalogue of the Striges in the Australian Museum, which appears to possess a good series of every species known to inhabit Australia and the adjacent islands, with the exception of *Ninox ocellata* and *Ninox rufa*, the latter being a good species in Dr. Ramsay's opinion, though Mr. Sharpe considered it to be the young of *N. connivens*. It is to be hoped that Dr. Ramsay will continue his useful catalogues of the specimens of birds in the Australian Museum.

DR. J. B. STEERE has just published his preliminary descriptions of new species discovered by the members of the expedition to the Philippine Islands. It is to be hoped that a complete memoir on this important exploration will be published later on, as the diagnoses set forth in the little *brochure* just issued are, in many cases, worse than useless.

IN the *Times* for September 9 we read the following note on "How to keep salt dry"—"The Dutch Indian Government offers a prize of 10,000 fl. for the best practical answer to the question in what manner the salt which is sold in Dutch India in small packets should be packed up so as to keep dry."

WE have received the general Guide to the Science and Art Museum, Dublin, under the directorship of V. Ball, LL.D., F.R.S. The Museum is divided into two parts. Part I., which is in the old museum buildings, deals with natural history, while Part II. treats of arts and industry, and is in the new buildings. In this Museum there are short printed labels attached to the specimens, and for the more important objects, descriptive tables containing "greater detail than even an ordinary hand-book could conveniently contain" are added. In some cases small maps are attached, indicating the localities where the objects were found. In this edition, which by the way is the first issued, the several branches of the collections are dealt with generally, and we are told that "hand-books will be prepared later on for some of them," which will add greatly to the interest of the objects concerned.

THE Observatory of Zi-ka-Wei, near Shanghai, has published vol. xv. of its *Bulletin Mensuel*, for the year 1889. This Observatory is equipped with the best self-recording and other instruments, and the volume in question contains, in addition to the usual tables of hourly observations, diagrams of the mean diurnal variations, and of the tracks of typhoons, as well as comparisons of the monthly means of magnetical and meteorological observations for the year 1889, and those of the previous 17 years. An appeal was made to the missionaries of the province of Kiang-nan to record thunderstorm observations, and some interesting results are published for each month. These storms occur most frequently between noon and midnight, and generally proceed from west to east; they mostly occur in July and August; there is also a second maximum in April; they most frequently occur with a falling barometer, and are generally accompanied with rain, but very rarely with hail. The work also contains interesting general remarks upon the depressions and cyclones of the coast of China.

THE Journal of the Asiatic Society of Bengal, three numbers of which we have received, contains some interesting papers on various subjects. In No. 1, Part 2 of vol. lix. there is a paper by John Eliot on the occasional inversion of the temperature relations between the hills and plains of Northern India. Alfred Alcock, Surgeon-Naturalist to the Marine Survey, contributes a paper on observations on the gestation of some sharks and rays, made on board H.M. Indian Marine Survey steamer *Investigator*, Commander Alfred Carpenter, R.N., while from the same ship we have descriptions of seven additional new Indian Amphipods by G. M. Giles, late Surgeon-Naturalist to the Survey. Asutosh Mukhopadhyay contributes three papers, as follows:—Note on Stokes's theorem and hydrokinetic circulation; on Clebsch's transformation of the hydrokinetic equation; and on a curve of aberrancy. The supplement to No. 1 of this part consists of a catalogue of the Insecta of the Oriental region and the order of Coleoptera, family Carabidæ, by E. T. Atkinson. The third pamphlet contains the title-page, index, &c., to vol. lvii. Part 2, 1888.

THE *American Meteorological Journal* for August contains the conclusion of M. Faye's articles on Trombes and Tornadoes. The author considers that the facts adduced show (1) that there are no centripetal movements, either at the foot of trombes or tornadoes, or toward the base of cyclones; (2) that these are descending whirls with vertical axes, originated in the upper currents of the atmosphere, and follow the direction of these currents. The same journal contains the tornado prize essays. The first prize has been awarded to Lieutenant J. P. Finley. The following are some of the general results arrived at:—Tornadoes generally accompany an area of low barometer. Their progressive motion to the north-east arises from the fact that as they always form in the south-east quadrant of an area of low barometer, they must come within the influence of the general drift of the atmosphere on that side of the low barometer which is always to the north-east. A hailstorm is an incipient tornado in the cloud-region of an area of low barometer. As the area of low barometer progresses eastward, the region lying on an average about 350 miles to the south and east of the centre of the general storm, is the region within which tornadoes may be expected. Tornadoes, with hardly an exception, occur in the afternoon, just after the hottest part of the day; the destructive power of the wind increases rapidly from the circumference of the storm to its centre. The months of greatest frequency, as determined from a period of over 200 years, are April to July; the average frequency of the storms does not appear to have changed within that time. The shortest time occupied by the tornado-cloud in passing a given point varies from an instant to about twenty minutes, the average time being 74 seconds. The second prize was awarded to Mr. A. McAdie.

A NEW method of measuring the inductive power and conductivity of dielectrics has been recently described by M. Curie in the *Annales de Chimie et de Physique*; it is based on the use of an apparatus he calls the piezo-electric quartz. He has studied with it those qualities in various crystalline dielectrics; and he enunciates a *law of superposition*, which shows the independence of the effects produced by different variations of electromotive force. Quartz shows a difference of conductivity in the direction of the optic axis (where it is strong), and at right angles (where it is insensible); and this gives rise to striking phenomena. Plates parallel to the axis, and with the extremities of the axis

communicating with the earth, behave, beyond 120°, as dielectrics of zero inductive power. With prolonged heating, the conductivity along the axis quite disappears. Water plays a capital *rôle* in the conductivity of a great many dielectrics (possibly in all). With plates of baked porcelain kept moist the various types of conductivity could be reproduced. The electromotive forces of polarization of moist porous bodies may attain several hundred volts.

PRAIRIE dogs, it appears from a recent letter by Dr. Wilder to *Science*, lack the sense of distance. At Cornell University, several individuals walked off chairs, tables, and window-sills unhesitatingly. This is thought to be due to the nature of their usual habitat, a plain, with no sharper inequalities than burrows and mounds. One adult female seemed to have wonderful immunity from the ill-effects of falls: it once fell from the top of an elevator 21 feet high, and another time from a window-sill, about as high, on a granite pavement, but soon recovered. These animals respond to sudden sound by erecting the body and barking, and the nervous mechanism involved seems to be largely reflex, rapidly exhausted, but nearly or quite uncontrollable; indeed, one of those falls seems to have been due to an unguarded erection of the body on hearing a large clock strike.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♂) from India, presented by Mr. Jesser Coope, F.Z.S.; a Nightingale (*Daulias luscinia*), British, presented by Mr. J. Young, F.Z.S.; two Green Doves (*Chalcophaps indica*) from Ceylon, presented by Mrs. Thompson; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Master E. S. Forwood; two Short-tailed Wallabys (*Halmaturus brachyurus*) from Australia, received in exchange; a Brown Capuchin (*Cebus fatuellus* ♂) from Brazil, a Squirrel Monkey (*Chrysothrix sciurea*) from Guiana, a Banksian Cockatoo (*Calyptorhynchus banksii*) from New South Wales, deposited; two Red-vented Bulbuls (*Pycnonotus hæmorrhous*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on September 11
21h. 24m. 28s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′

(7) S Vulpeculæ	Var.	Yellow-red.	19 43 53	+27 1

Remarks.

(1) In the General Catalogue this nebula is described as "a very remarkable object; pretty bright; considerably large; extremely irregular figure; *k* Cygni involved." The spectrum, as observed by Dr. Huggins, is a continuous one with a suspicion of an unusual brightness in the region beyond F. The excess of blue light is probably due to the radiation of some substance, most likely carbon, added to a dim and short continuous spectrum. The green flutings would in that case be masked by continuous spectrum, and the result would be a spectrum apparently continuous in the green and discontinuous in the blue. This discontinuity should be looked for in the nebula spectrum, and comparisons made with the carbon flutings.

(2) This star has a spectrum of Group II. "of extraordinary beauty," all the bands 1–9 being very wide and very dark (Dunér). It is probably a star of mean condensation, and the bright carbon flutings should therefore be well seen.

(3) The spectrum of this star may advantageously be studied in connection with the observations of stars which have a spectrum hitherto described as of the solar type. It is one of a very late stage of Group II., the distinctive dark bands being very narrow, so that the spectrum approaches one of Group III. The *lines* which are seen at this stage will in all probability be continued to Group III. stars, and will therefore serve as criteria for distinguishing between stars of Group III. and stars of Group V.

(4) Vogel writes the spectrum of this star as II.*a* (I.*a*), which means that the star is either at a late stage of Group III., or an early one of Group V. Its precise position on the "temperature-curve" may be determined by reference to the criteria mentioned in the note on (3).

(5) The spectrum of this star is one of Group IV.

(6) Although this star is far from being a faint one compared with many other stars of Group VI., very few details have been observed in its spectrum, either by Secchi or Dunér. Dunér simply states that the spectrum consists of three zones, the blue being very weak. The intensity of band 6 (λ 564) relatively to band 9 (λ 517), and other details, should be noted.

(7) This is a variable of Group II. of very small range and short period. The mean magnitude at maximum is about 8·85, and that at minimum 9·95. The mean period is about 67·8 days, and the increase to maximum is much more rapid than the decrease to minimum, the former occupying 20·6 days, and the latter 47·2. According to Dunér, the spectrum is only feebly developed, and this is exactly what it should be if Mr. Lockyer's view as to the constitution of this class of bodies be correct. The central swarm being well advanced in condensation, only revolving swarms of short period will be effective in producing changes of light, because long period swarms will pass clear of the central swarm at periastron. It is only to be expected, therefore, that a well advanced, or "feebly-developed" spectrum should be associated with a short period in variables of Group II. Under these circumstances it is not likely that bright hydrogen lines will appear at maximum, but an observation of their absence will be of value, and other variations may occur. There will be a maximum about September 15.

A. FOWLER.

OBSERVATIONS OF THE COMPANIONS TO BROOK'S COMET (V. 1889).—Mr. E. E. Barnard, in *Astronomische Nachrichten*, No. 2988, gives the physical and micrometrical observations of the companions to this comet made with the 12-inch and 36-inch refractors of the Lick Observatory, and those made elsewhere. It will be remembered that Mr. Barnard discovered two companions to Brook's comet on August 2, 1889, and two others on August 5. His remarks on the appearance of the companions, and the physical changes which they underwent from the date of discovery, until they disappeared from sight, are very important. Two of the companions seemed to undergo the same process of disintegration. Beginning with a nucleus and a tail, each became enlarged, diffused, and fainter, until it had dissipated into space. In some concluding remarks Mr. Barnard writes: "I have no doubt but that the great telescope would readily reveal more unknown nebulæ than the entire number now contained in the latest catalogue of Dreyes," and the number of unknown nebulæ incidentally found by him during these observations supports this assertion.

PARALLAX OF β ORIONIS.—In the *Observatory* for September, Dr. Gill has a note on the parallax of β Orionis. The star is situated near one corner of the nebulous area encircled by α Orionis, Lalande 11382, Lalande 11329, ω Orionis, ψ Orionis, and β Eridani, and the observations show that it has a negative parallax of about 0″·17 relative to the near parallax of the stars D.M. − 7° 997 and − 8° 1078, and therefore belongs to a more distant system. It also results from the calculations that the former star and θ Orionis are members of an immensely more remote system than the latter one. The reductions were suggested by an examination of a photograph of the region about the Orion nebula taken under the direction of Prof. E. C. Pickering.

CARL FREDERIK FEARNLEY.—The death of this eminent Norwegian astronomer occurred on the 23rd ult. at Christiania. He was born at Frederikshald on December 19, 1818. In 1844 he became attached to the Observatory of Christiania University as an assistant, and since 1861 has been the Director. He was made a Professor of Astronomy in 1857.

The deceased astronomer published many observations of planets, comets, and the sun, and directed some attention to the determination of the height of the aurora borealis. He also published a memoir on atmospheric refraction, and participated in many geodetical observations.

Fearnley's death is severely felt by those with whom he came in contact.

UNITED STATES NAVAL OBSERVATORY, WASHINGTON.—The report of the superintendent of the U.S. Naval Observatory for the year ending June 30, 1889, has just been issued, and contains an account of the work done in each department.

The large equatorial has been employed in observing double stars and the satellites of Saturn; attention also being paid to the division on the ring and to the shadows.

Seventeen hundred observations have been made with the transit circle since October 9, 1888; of this number 68 were of the sun, 60 of the moon, 93 of the major planets, 18 of the minor planets, and 5 of Comet *e* 1888.

The 9·6-inch equatorial has been used for the identification of stars whenever necessary, and for the observations of small planets, comets, and occultation of stars by the moon. During the past year 3 comets were seen and observed whenever possible. Two nights a week this instrument is set apart for the accommodation of visitors, and permits for 1665 visitors were issued.

Assistant-Astronomer H. M. Paul, who has for the last year and a half been here observing suspected variables, has just discovered a new variable in the constellation Antlia, with a period of less than 12 hours, the shortest period yet known.

The chronometer and time service, under the charge of Lieutenant Taylor, have been doing good work. Fifty-six chronometers received from the makers, cleaned, and repaired, were tested in the temperature-room for a period of about two months. Chronometers were issued to eleven ships and one shore station, and the same number were received back.

No alteration has been made in the routine of sending out time signals, which are telegraphed every day, Sundays and holidays excepted.

In the magnetic department under the charge of Ensign Marsh, observations have been made on Tuesdays each week for the determination of the absolute horizontal intensity, and on each month they were made with the inertia cylinder attached to the magnet. Observations on the magnetic inclination, using three needles in rotation, were made every Monday and Friday. Two seismoscopes and a seismograph have been added to the stock of instruments, and they have been set up and are in good working order.

The library, which has lately been placed under the charge of Assistant-Astronomer Paul, in addition to his other duties, contains, up to June 30, 12,226 volumes and 2696 pamphlets, of which the accessions, since the last Report, have been 308 in number, 235 volumes and 73 pamphlets.

The appendix contains a report of the work done during the past year, by Prof. William Harkness, who was attached for special duty as a member of the Transit of Venus Commission, and had charge of the reductions and computations of the observations of 1874 and 1882. The result of his work is the determination of the sun's distance to be 92,455,000 miles, with a probable error of 123,400 miles.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, September 3.—Mr. Henry T. Stainton, F.R.S., in the chair.—Mr. C. Fenn exhibited and remarked on specimens of *Eupithecia satyrata*, *Eudorea ambigualis*, and *Tortrix viburnana* from Darlington.—Mr. H. Goss exhibited, on behalf of Mr. Martin S. Higgs, a remarkable variety of *Melitæa aurinia* (*artemis*), taken a few years ago, in Gloucestershire, by Mr. Joseph Merrin.—The Rev. Dr. Walker communicated some observations on the entomology of Iceland, and gave an account of his recent travels in that island. He stated that he had taken *Bombus terrestris* this year, for the first time, in the north-west of Iceland, from which quarter of the island it had not been recorded by Dr. Staudinger; he also referred to the enormous numbers of Ichneumonidæ and Diptera which he had noticed in the island. He further stated that in 1889, in the months of June and July, *Noctua conflua* was the most abundant species of Lepidoptera in Iceland; but that this year, in July and August, *Crymodes exulis* was the prevailing species, and that *Charæas graminis* and *Coremia munitata* also occurred in great numbers. In reply to a question by Mr. Stainton, Dr. Walker said that the flowers chiefly frequented by the humble-bees were those of a small species of white Galium (probably *Galium saxatile*) and *Viola tricolor*. Dr. Walker also read notes on *Calathus melanocephalus* collected in Iceland and the Faroe Isles in June and July 1890. Messrs. M'Lachlan, Stainton, Jenner Weir, Stevens, Jacoby, Lewis, and others took part in the discussion which ensued.—Mr. Arthur G. Butler communicated a paper entitled "Further Notes on the Synonymy of the Genera of Noctuites."

PARIS.

Academy of Sciences, September 1.—M. Duchartre in the chair.—MM. G. Seguy and Verschaffel gave a description of a photometer founded upon the principle of Crooke's radiometer.—M. Faye announced the publication of the *Connaissance des Temps* for 1892.—Influence of altitude on the development of plants, by M. Gaston Bonnier. The author has observed that the amount of carbon dioxide decomposed by plants increases with the altitude. Plants cultivated in an Alpine climate undergo a modification of their functions such that the chlorophyllian assimilation and transpiration are augmented, whilst respiration and transpiration in the dark appear little modified or slightly diminished.—On the chlorophyllian assimilation of trees with red leaves, by M. Henri Jumelle. The author has investigated the difference of physiological functions in the leaves of the green and red type of such trees as the beech, sycamore, elm, &c. He finds: (1) in trees with red or coppery-coloured leaves the chlorophyllian assimilation is always more feeble than in trees of the same kind having green leaves; (2) the intensity in the copper beech and purple sycamore is only about one-sixth that of the ordinary types of the same trees.—On the oospores formed by the fusion of multi-nuclei sexual elements, by M. P. A. Dangeard. The author has studied the sexual reproduction of plants of a lower order.—First observations on the cyclone of August 19 in Jura, by M. Bourgeat. A circumstantial account of the St. Claud cyclone is given. It is noted that the lower parts of the region visited by the storm suffered the most, that the direction of the gyratory movement was opposite to that of the hands of a watch, that the velocity of translation was about 1 kilometre a minute, and that the zone ravaged had a breadth from 500 to 1000 metres.—On the signification of the word "cyclone," by M. H. Faye. It was remarked by M. Faye that although all the papers and the author of the preceding note had named the St. Claud storm a cyclone, yet really it was a tornado. The difference between the two phenomena was pointed out, it being noted that the base of a cyclone is considerably larger than that of the St. Claud storm, and has a well-defined region of calm at its centre.

THURSDAY, SEPTEMBER 18, 1890.

THE ABORIGINES OF TASMANIA.

The Aborigines of Tasmania. By H. Ling Roth. (London: Kegan Paul, Trench, Trübner, and Co., 1890.)

MR. H. L. ROTH has written an honest, unpretentious, and therefore most useful book on "The Aborigines of Tasmania." He gives us on pp. 2–8 a very complete bibliography of all works treating of his subject, and he then proceeds to place before us the quintessence distilled from that little library. Why he should have printed two hundred copies only of his work, is difficult to understand, and does not speak well for the study of anthropology. No serious student of human palæontology can be without this book, and we should have supposed that the public at large also would have much preferred a trustworthy description of the life and manners of this now extinct race to the ever-varying theories of what a savage is supposed to have been or not to have been, to have done or not to have done, which abound in some of the most popular works on anthropology and sociology. In the fourteen chapters of his book Mr. Roth treats of the country, the form and size of its inhabitants, the psychology of the natives, their wars, their knowledge of fire, hunting, and fishing, their nomadic life, their personal habits, their scientific and artistic acquirements, their manufactures, their trade, their customs, good and bad, their language, their osteology, and lastly their origin.

It would be impossible to give an idea of the wealth of information on all these subjects which Mr. Roth has rendered accessible in this volume. It is well arranged, and all his statements can readily be verified, for he always give his references, and a complete index renders its use easy at all times. The illustrations also show great care and cleverness.

Perhaps not the least important lesson which anthropologists might learn from this book is the extremely uncertain character of the accounts which visitors of Tasmania, and even persons long settled in the island, have given us of its inhabitants. This is a sore point with the students of sociology, but it is high time that it should be thoroughly probed. We shall confine our remarks to one subject only, the Tasmanian religion, and, with the help of Mr. Roth, we shall undertake to show that there is not one essential point in the religion of the Tasmanians on which different authorities have not made assertions diametrically opposed to each another.

No Religion.—Nothing staggers a savage—perhaps even an educated man—so much as when he is asked what his religion is. No wonder that many of the Tasmanians, when asked that question, answered, with a broad grin, "Don't know." What should we say if we were asked whether we believed in *Raegoo Wrapper* or *Namma?* Widowson, however, assures us that the Tasmanians had really no religion at all. "It is generally supposed," he says, "that they have not the slightest idea of a Supreme Being." Briton adds: "They do not appear to have any rites or ceremonies, religious or otherwise."

Dualism.—That the Tasmanians were Dualists, believing, like the followers of Zoroaster, in a good and an evil spirit, is attested by numerous authorities. Leigh says:—"Their notions of religion are very obscure. However, they believe in two spirits: one, they say, governs the day, whom they call the good spirit; the other governs the night, and him they think evil. To the good spirit they attribute everything good, and to the evil spirit everything hurtful." Jeffreys says:—"They have but a very indistinct notion of their imaginary deity, who, they say, presides over the day, an evil spirit making its appearance in the night. This deity, whosoever it is, they believe to be the giver of everything good." He adds, however, that they appear to acknowledge no more than one God, thus furnishing an exact parallel to the Parsis, who, though they admit two spirits, acknowledge Ormasd only as their true god. Milligan confirms this view. He admits that the Tasmanians believed in many spirits, but he adds that "they considered one or two spirits to be of omnipotent energy, though they do not seem to have invested even these last with attributes of benevolence." Robinson maintains that "they were fatalists (whatever that may mean in their language), and that they believed in the existence both of a good and evil spirit. The latter they called *Raegoo Wrapper*, to whom they attributed all their afflictions, and they used the same word to express thunder and lightning."

Nature-Gods.—That the Tasmanians derived some of their ideas of the godhead from the great phenomena of Nature we have seen already from their identifying day and night with their good and evil spirits. Thunder and Lightning were their names for the evil spirit, or their devil, as some observers call him. Besides day and night, thunder and lightning, the moon also is mentioned as an object of their worship. Thus, Lloyd tells us "that it was customary among the aborigines to meet at some time-honoured trysting-place at every full moon, a period regarded by them with most profound reverence." Indeed, he adds, "judging from their extraordinary gestures in the dance, the upturned eye and outstretched arm, apparently in a supplicating spirit, I have been often disposed to conclude that the poor savages were invoking the mercy and protection of that planet as their guardian deity."

Devil-worship.—We now come to the testimony in support of an exclusive devil-worship. Davies asserts that the aborigines certainly believed in the existence of an evil spirit, called by some tribes Namma, who has power by night. Of him they are much afraid, and never will willingly go out in the dark. But, he adds, "I could never make out that they believed in a good deity, for although they spoke of one, it struck me that it was what they had been told; they may, however, believe in one who has power by day."

Backhouse speaks in the same hesitating tone:—

> "These people," he says, "have received a few faint ideas of the existence and superintending providence of God; but they still attribute the strong emotions of their minds to the devil, who, they say, tells them this or that, and to whom they attribute the power of prophetic communication. It is not clear that by the devil they mean anything more than a spirit; but they say he lives in their breasts, on which account they shrink from having the breast touched."

If we could fully trust this statement, and it is confirmed to some extent by Horton, it would be most important as showing the germs of moral ideas among the Tasmanians. To believe in a devil, not simply with horns and hoofs, but living within our own hearts, is an advance which, even in Europe, has as yet been made by a small minority only. The majority of Tasmanians evidently represented their devil in a more material form. Thus Dove says that, "while they had no term in their native language to designate the Creator of all things, they stood in awe of an imaginary spirit who was disposed to annoy and hurt them. The appearance of this malignant demon in some horrible form, was especially dreaded in the season of night."

Monotheism.—But while some authorities seem inclined to reduce the Tasmanian religion to a belief in a devil only, others seem to look upon it as almost monotheism. Thus Jeffreys, though he admits that the Tasmanians (like most Agnostics) have a very indistinct notion of their imaginary deity, relates that they have a kind of song which they chant to him. He knows that they believe in a good and an evil spirit, but he adds, that they believe the good spirit to be the giver of everything good, and that they do not appear to acknowledge any more than one God. That good spirit had, as we saw, no name, and this, which to some may seem to be a serious defect, is again a feature which the Tasmanian religion shares in common with the religion of far more advanced races.

Spirit-worship.—Those who hold that religion began everywhere with a belief in spirits may likewise find some support for their theory in the accounts given of the Tasmanians. Henderson states:—

"A common belief prevails in Tasmania and New South Wales regarding the existence of inferior spirits, who conceal themselves in the deep woody chasms during the day, but who wander forth after dark, with power to injure or even to destroy. Their rude encampments are frequently alarmed by these unearthly visitors, whose fearful moanings are at one time borne on the midnight breeze, and at another are heard mingling with the howling tempest."

This does not prove as yet that these spirits are always believed to be the spirits of the departed. Milligan, however, after telling us that the Tasmanians were polytheists—that is, that they believed in guardian angels or spirits, and in a plurality of powerful but generally evil-disposed beings, inhabiting crevices and caverns of rocks, and making temporary abode in hollow trees and solitary valleys, adds "that the aborigines were extremely superstitious, believing most implicitly in the return of the spirits of their departed friends and relations to bless or injure them, as the case might be. To their guardian spirits, the spirits of their departed friends or relations, they gave the generic name *Warrawah*, an aboriginal term signifying shade, shadow, ghost, or apparition."

Immortality of the Soul.—One point on which nearly all witnesses seem to agree is the belief of the Tasmanians in the immortality of the soul. They evidently had not yet advanced so far as to be able to doubt it. Milligan had ascertained that the aborigines of Tasmania, previous to their intercourse with Europeans, distinctly entertained the idea of immortality, as regarded the soul or spirit of man. Robinson, who was present at the burning of a dead body, received the following explanation from a native:—"Native dead, fire; goes road England, plenty natives England." What he meant to say was that when a black fellow was dead and had been burnt, he went to England, where there are many black fellows. The name of England, *Dreany*, as a distant country, and the home of white people, had become with them the name of a new Elysium. Others expected to reappear on an island in the Straits, and to jump up white men. They anticipated in another life the full enjoyment of what they coveted in this. Backhouse declares that they have some vague ideas of a future existence. Dove remarks that they were persuaded of their being ushered by death into another and happier state, and he considers this as almost the only remnant of a primitive religion which maintained a firm abode in their minds. However, as if to show that no account of their religious persuasions should go uncontradicted, Davies remarks that, "though it is hard to believe that the natives have no idea of a future state, yet from every inquiry, both from themselves and from whites most conversant with them, I have never been able to ascertain that such a belief exists."

Prayers.—Of course those who maintain that the Tasmanians have no religion, maintain at the same time that they have no kind of worship, no sacrifices, no prayers. But Leigh tells us that, "when any of the family are on a journey, they are accustomed to sing to the good spirit for the purpose of securing his protection over their absent friends, and that they may be brought back in health and safety." Jeffreys relates that it frequently happens that the sealers . . . are compelled to leave their native women for several days together. On these occasions these affectionate creatures have a kind of song, which they chant to their imaginary deity.

Charms.—It is known also that the Tasmanians carried charms, mostly a bone or even the skull of their relatives and friends. In some cases they ascribed healing powers to these bones, or at all events they put them by their side or on their head when they felt sick. This after all is no more than our preserving a lock of hair, and looking at it when we are in trouble or grief.

Negative evidence is always less trustworthy than positive. Still it may be taken for what it is worth, that observers seem never to have discovered idols (p. 69), totems (p. 75), or fetishes, among the natives of Tasmania.

Such is the nature of the evidence bearing on the religious ideas of the Tasmanians, which Mr. Roth has collected so carefully and so conscientiously. Nothing can be more full of contradictions, more doubtful, more perplexing. Yet with such materials our best anthropologists and sociologists have built up their systems.

The Tasmanians, being reputed the lowest of savages, were represented as the children of Nature, and whatever the children of Nature were supposed to have been, when emerging from a purely animal into a more or less human state, the Tasmanians and other savages were called up as witnesses to confirm every kind of psychological speculation.

We saw that there is hardly any kind of religion which could not be proved to have been the original religion of the Tasmanians. How then can we wish for more

pliant witnesses in support of any theory as to what the primordial religion of mankind must have been? If it were desired to prove that, prior to the advent of Europeans, they were atheists, without any religious ideas or ceremonial usages, we have several excellent witnesses to prove it. We could prove equally well that they believed in a devil only, that they were Dualists, believing in a good and an evil spirit, that they had deified the powers of Nature, that they had arrived at a belief in one God, that they were polytheists, that they believed in ghosts, in the return of the spirits of their friends, in the immortality of the soul, and in the efficacy of prayers and charms. Nay, if it were desired to produce perfectly unprejudiced evidence in favour of the descent of man from some higher animal, Lord Monboddo might have appealed to the Tasmanians. For, according to Mr. Horton, they believed "that they were formed with tails and without knee-joints, by a benevolent being, and that another descended from heaven, and compassionating the sufferers, cut off their tails, and with grease softened their knees."

Dr. E. B. Tylor, F.R.S., the Reader in Anthropology at Oxford, has written a short preface, in which he expresses his general approval of the work.

F. MAX MÜLLER.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

British Association Procedure.

THERE is one point on which I am unable to agree with Prof. Tilden's letter in your issue of September 4 (p. 456), viz. that concerning the work and constitution of the Sectional Committees. I can only speak in terms of Section A, but I believe that whatever cynical doubt may be expressed as to the utility of the proceedings of the Section there is none as to the utility of its proceedings in Committee. Here matters of moment are brought forward, suggestions made, new researches encouraged or the reverse; and here, as Mr. Shenstone implies, younger members become acquainted with those whom they have long revered at a distance. A sectional committee is not, and should not be, a small executive body, but a large, representative, and suggestive body comprising all the real workers in the particular subject present at the year's gathering, and by no means excluding those younger men who, though now retiring and inconspicuous, will have at some future time to take a prominent place.

Prof. Tilden speaks, however, of the *demand* for election upon the sectional committees.

If there is anything of this sort, and I believe that to some extent there is, it is an abuse to be checked with vigour.

I should like to propose a general agreement that any direct demand or solicitation to be placed on any committee should be accepted as at once disqualifying for that year. But all the more would it be incumbent on accustomed members to see that no real original worker was accidentally excluded from the healthy and stimulating conference with his seniors which these meetings may afford.

OLIVER J. LODGE.

The Mode of Observing the Phenomena of Earthquakes.

Forwarded by Dr. John Marshall.

HAVING seen in NATURE, of the 28th ult. (p. 414), remarks, on the uncertainty of the evidence to be obtained a narration of the subjective impression of movements of the earth and surrounding objects, in obtaining information with regard to earthquakes, and that you also remark that, "possibly, some evidence on this subject might even now be obtained," I venture to say that I was in a first storey room of Wickham Place, near Witham, Essex, during the earthquake that occurred somewhat severely in part of Essex a few years back; and that I was sitting against a partition wall, facing a window to the east, during the whole time of its duration. A hill about 1½ miles away formed the horizon, the outline of which passed across this window about half way up, from my point of view. I saw this outline apparently rise up to the top of the window, and sink down again, a displacement which, if it had been due to the movement of the hill itself, must have meant a great deal; but although this was really due, no doubt, to the motion of the house itself, yet the appearance was so deceptive that it produced entirely the idea, at the time, on my senses, that it was the hill that moved.

At Guy's Hospital last year, about 14 months ago, while I was in bed, at somewhere about eight o'clock, I fancy, I felt nothing, but saw the other parts of the building, through the windows, sway slowly, and the sight of it gave me a more or less dizzy feeling. There was a friend sitting on the bed at the time, but he felt nothing. Until I drew his attention to the fact that the bed curtains were swaying, he saw nothing of it.

These impressions make me think that such are of no value in a house except to determine very slight shocks.

I made notes at the time of these points, but they are not to hand just now. I scarcely think such evidence can be of any use to you, but on the chance that it may be, I send it.

HAROLD G. DIXON.

Nelson House, Shanklin, Isle of Wight, September 3.

THE BRITISH ASSOCIATION.

SECTION F.

ECONOMIC SCIENCE AND STATISTICS.

OPENING ADDRESS BY PROF. ALFRED MARSHALL, M.A., F.S.S., PRESIDENT OF THE SECTION.

Some Aspects of Competition.

I UNDERSTAND that the function of an opening address to a section of this Association is to give an account of the advances made in some part of the field of study with which that section is specially concerned. The part of our field to which I would direct your attention to-day is the action of competition. We cannot, in the short space of time allotted to us, make an adequate study of the progress that has been made even in this part of our field; but we may be able to go some way towards ascertaining the character of the changes that are going on in our own time in the mode of action of competition, and in the attitude of economists towards it.

I do not now speak of changes in the moral sentiments of economists with regard to competition—though these, also, are significant in their way—but of changes in their mental attitude towards it, and in the way in which they analyse and reason about its methods of action. Of these changes, the most conspicuous and important is the abandonment of general propositions and dogmas in favour of processes of analysis and reasoning carefully worked out, and held ready for application to the special circumstances of particular problems relating to different countries and different ages, to different races and different classes of industry.

This movement may, perhaps, best be regarded as a passing onward from that early stage in the development of scientific method, in which the operations of Nature are represented as conventionally simplified for the purpose of enabling them to be described in short and easy sentences, to that higher stage in which they are studied more carefully, and represented more nearly as they are, even at the expense of some loss of simplicity and definiteness, and even apparent lucidity. To put the same thing in more familiar words, the English economists of fifty years ago were gratified, rather than otherwise, when some faithful henchman, or henchwoman, undertook to set forth their doctrines in the form of a catechism or creed; and the economists of to-day abhor creeds and catechisms. Such things are now left for the Socialists.

It has, indeed, been an unfortunate thing for the reputation of the older economists, that many of the conditions of England

at the beginning of this century were exceptional, some being transitional, and others, even at the time, peculiar to England. Their knowledge of facts was, on the average, probably quite as thorough as that of the leading economists of England or Germany to-day, though their range was narrow. Their thoroughness was their own, the narrowness of their range belonged to their age; and though each of them knew a great deal, their aggregate knowledge was not much greater than that of any one of them, because there were so few of them, and they were so very well agreed. In these matters we economists of to-day have the advantage over them.

Their agreement with one another made them confident; the want of a strong opposition made them dogmatic; the necessity of making themselves intelligible to the multitude made them suppress even such conditioning and qualifying clauses as they had in their own minds: and thus, although their doctrines contained more that was true, and new, and important than those promulgated by almost any other set of men that have ever lived—doctrines for which they will be gratefully remembered as long as the history of our century retains any interest—yet, still, these doctrines were so narrow and inelastic that, when they were applied under conditions of time and place different from those in which they had their origin, their faults became obvious and created a reaction against them.

Perhaps the greatest danger of our age is that this reaction may be carried too far, and that the great truths which lie embedded in these too large utterances may be neglected because they are not new, and men are a little tired of them; and because they are associated with much that is not true, and which has become, not altogether unjustly, repugnant to men's sentiments.

The most important instances of this kind are, perhaps, to be found in connection with the relations between competition and combination in trade and industry. But I will first refer briefly to the relations between protection and free trade in foreign commerce, because these have a longer and more fully-developed history.

It is a constant source of wonder to Englishmen that protection survives and thrives, in spite of the complete refutations of protectionist arguments with which English economists have been ready to supply the rest of the world for the last fifty years or more. I believe that these refutations failed chiefly because some of them implicitly assumed that whatever was true as regards England, was universally true; and if they referred at all to any of the points of difference between England and other countries, it was only to put them impatiently aside, without a real answer to the arguments based on them. And further, because it was clearly to the interests of England that her manufactures should be admitted free by other countries, therefore, any Englishman who attempted to point out that there was some force in some of the arguments which were adduced in favour of protection in other countries, was denounced as unpatriotic. Public opinion in England acted like the savage monarch who puts to death the messenger that comes running in haste to tell him how his foes are advancing on him; and when John Stuart Mill ventured to tell the English people that some arguments for protection in new countries were scientifically valid, his friends spoke of it in anger—but more in sorrow than in anger—as his one sad departure from the sound principles of economic rectitude. But killing the messengers did not kill the hostile troops of which the messengers brought record; and the arguments which the Englishmen refused to hear, and therefore never properly refuted, were for that very reason those on which protectionists relied for raising a prejudice in the minds of intelligent and public-spirited Americans against the scientific soundness and even the moral honesty of English economics.

The first great difficulty which English economists had, in addressing themselves to the problems of cosmopolitan economics, arose from the fact that England was an old country—older than America in every sense, and older than the other countries of Europe in this sense, that she had accepted the ideas of the new and coming industrial age more fully and earlier than they did. In speaking of England, therefore, they drifted into the habit of using, as convertible, the two phrases—"the commodities which a country can now produce most easily," and "the commodities which a country has the greatest natural advantages for producing," that is, will always be able to produce most easily. But these two phrases were not approximately convertible when applied to other countries; and when List and Carey tried to call attention to this fact, Englishmen did little more than repeat old arguments, which implicitly assumed that New England's inability to produce cheap calico had the same foundation in natural laws as her inability to produce cheap oranges. They refused fairly to meet the objection that arguments which prove that nothing but good can come from a constant interchange of goods between temperate and tropical regions, do not prove that it is for the interest of the world that the artisans who are fed on American grain and meat should continue always to work up American cotton for American use three thousand miles away. Finding that their case was not fairly met, the protectionists naturally thought it stronger than it was, and honestly exaggerated it in every way. One of my most vivid recollections of a visit I made in 1875, to study American protection on the spot, is that of Mr. Carey's splendid anger, as he exclaimed that foreign commerce had made even the railways of America run from east to west, rather than from north to south.

England had passed through the stage of having to import her teachers from other lands. But her genius for freedom had attracted to her shores the pick of the skilled artisans of the world; she had received the best lessons from the best instructors, and seldom paid them any fee, beyond a safe harbour from political and religious persecution. And modern Englishmen could not realize, as Americans, and even Germans, could, fifty years ago the difficulties of a manufacturer taking part in starting a new industry, when he came to England to beg or steal a knowledge of the trade, and to induce skilful artisans to come back with him. He seldom got the very best; for they were sure of a comfortable life at home, and were perhaps not without some ambition of rising to be masters themselves. He had to pay their travelling expenses, and to promise them very high wages; and when all was done, they often left him to become the owners of the 160 acres allotted to every free settler; or, the bitterest pill of all, they sold their skill to a neighbouring employer who had been looking on at the experiment, and, as soon as it showed signs of prosperity, stepped in, improved on the first experiments, and reaped a full harvest on a soil that had been made ready by others.

Again, the pioneer manufacturer had to bring over specialized machinery, and specialized skill to take care of it. If any part went wrong, or was superseded, the change cost him ten times as much as his English competitor. He had to be self-sufficing: he could get no help from the multitude of subsidiary industries, which in England would have lent him aid at every turn. He had a hundred pitfalls on every side: if he failed, his failure was full of lessons to those who came after; if he succeeded, the profits to himself would be trivial, as compared with those to his country. When he told the tale of his struggles, every word went home to his hearers; and when the English economists, instead of setting themselves to discover the best method by which his country might help him in his experiment, said he was flying in the face of Nature, and called him a selfish schemer for wanting any help at all, they put themselves out of court.

But the failure of English economists to allow for the special circumstances of new countries did not end here. They saw that protective taxes in England had raised the price of wheat by their full amount (because the production of wheat obeys the law of diminishing return; and in an old country, such as England, increased supplies could be raised only at a more than proportionately increased cost of labour); that the high price of bread had kept a large part of the population on insufficient rations; that it had enriched the rich at the expense of a much greater loss to the rest of the nation; and that this loss had fallen upon those who were unable to lose material wealth without also losing physical, and even mental and moral strength; and that even those miseries of the overworked factory women and children, which some recent German writers have ascribed exclusively to recklessness of manufacturing competition in its ignorant youth, were really caused chiefly by the want of freedom for the entry of food. They were convinced, rightly, as I believe, that the benefits claimed for protection in England were based, without exception, on false reasoning; and they fought against it with the honest, but also rather blind, energy of a religious zeal.

Thus they overlooked the fact that many of those indirect effects of protection which aggravated then, and would aggravate now, its direct evils in England, worked in the opposite direction in America. For, firstly, the more America exported her raw produce in return for manufacture, the less the benefit she got from the law of increasing return as regards those goods

that she manufactured for herself; and thus her case was contrasted with England, who could manufacture them more cheaply for her own use the more of her manufactures she sent abroad to buy raw produce; and for this and other reasons a protective tax did not nearly always raise the cost of goods to the American consumer by its full amount. And, secondly, protection in America did not, as in England, tax the industrial classes for the benefit of the wealthy class of landlords. On the contrary, in so far as it fell upon the exporters of American produce, it pressed on those who had received large free gifts of public land; and there was no *primâ facie* injustice in awarding to the artisans, by special taxation, a small part of the fruits of that land, the direct ownership of which had not been divided between farmers and artisans, as it equitably might have been, but had been given exclusively to the former.

I have touched on but a few out of many aspects of the problem. But perhaps I may stop here, and yet venture to express my own opinion on the controversy. It is, that fifty years ago it might possibly have been not beyond the powers of human ingenuity to devise schemes of protection which would, on the whole, be beneficial to America, at all events if one regarded only its economic and neglected its moral effects; but that the balance has turned strongly against protection long ago. In 1875 I walked up and down some of the streets of nearly all the chief American cities and said to myself as I went—The adoption of free trade, so soon its first disturbances were over, would strengthen this firm, and weaken that; and I tried to strike a rough balance of the good and evil effects of such a change on the non-agricultural population. On the whole, it seemed to me the two were about equally balanced. Taking account, therefore, of the political corruption which necessarily results from struggles about the tariff in a democratic country, and taking account also of the interests of the agricultural classes, I settled in my own mind the question as to which I had kept an open mind till I went to America, and decided that, if an American, I should unhesitatingly vote for free trade. Since that time the advantages of protection in America have steadily diminished, and those of free trade have increased; I can see no force in Prof. Patten's new defence of protection as a permanent policy. I have already implied that I believe that many of those arguments that tell in favour of protection as regards a new country tell against it as regards an old one. Especially for England a protective policy would, I believe, be an unmixed and grievous evil.

But this expression of my own opinion is a digression. My present purpose in discussing protection is to argue that, if the earlier English economists had from the first studied the conditions of other countries more carefully, and abandoned all positions that were at all weak, they could have retained the controversy with their opponents within those regions where they had a solid advantage. They would thus have got a more careful hearing when they claimed that, even though labour migrated more freely between the west and the east of America than between England and America, yet it was unwise to spend so much trouble on protecting the nascent industries of the East against those of England, and none on protecting the nascent industries of the west against those of the east; or, again, when they urged that, the younger an industry was, and the more deeply it needed help, the more exclusively would its claims have to stand on its own merits; while its older and sturdier brothers could supplement their arguments by a voting power which even the most honest politicians had to respect, and by a power of corruption which would tend to make politics dishonest.

Had the English economists been more careful and more many-sided, they would have gradually built up a prestige for honesty and frankness, as well as for scientific thoroughness, which would have inclined the popular ear to their favour, even when their arguments were difficult to follow. Intellectual thoroughness and sincerity is its own reward; but it is also a prudent policy when the people at large have to be convinced of the advisability of a course of action against which such plausible fallacies can be urged as that "protection increases the employment of domestic industries," or that "it is needed to enable a country in which the rate of wages is generally high to carry on trade with another in which it is generally low." The arguments by which such fallacies can be opposed have an almost mathematical cogency, and will convince, even against his will, any one who is properly trained for such reasonings. But the real nature of foreign trade is so much disguised by the monetary transactions in which it is enveloped, that a clever sophist has a hundred opportunities of throwing dust in the eyes of ordinary people, and especially the working classes, when urging the claims of protection as affording a short cut to national prosperity; and, to crown all, he contrasts America's prosperity with English prophecies of the ruin that protection would bring on her.

It is true that Ricardo himself, and some of those who worked with him, were incapable of supposing that a doctrine can be made more patriotic by being made less true; and, so far as their limits went, they examined the good and evil of any proposed course, and weighed the good and evil against one another in that calm spirit of submissive interrogation with which the chemist weighs his materials in his laboratory. But they were few in number, and their range of inquiry was somewhat narrow; while many of those Englishmen who were most eager to spread free trade doctrines abroad had not the pure scientific temper.

Now at length, however, there seems to be the dawn of a brighter day in the growth of large numbers of many-sided students, in England and other countries, and notably in America itself, where the problems of protection can be studied to most advantage—students who are not, indeed, without opinions as to what course it is most expedient to follow practically, but who are free from party bias, and have the true scientific delight in ascertaining a new fact or developing a new argument, simply because they believe it to be new and true, and who welcome it equally whether it tells for or against the practical conclusion which, on the whole, they are inclined to support.

But I must leave the subject of competition from outside a nation, and pass to that of competition within. Here the past counts for less; the present and the future have to work for themselves without very much direct aid from experience. For, rapid as are the changes which the last few years have seen in the conditions of foreign trade, those which are taking place in the relations of different groups of industry within a country are more rapid still, and more fundamental. The whirligig of Time brings its revenges. It was to England's sagacity and good fortune in seizing hold of those industries in which the law of increasing return applies most strongly that she owed in a great measure her leading position in commerce and industry. Time's revenge was that that very law of increasing return furnished the chief motive to other countries, and especially America, to restrict their commerce with her by protective duties to home industries. And Time's counter-revenge is found in this—that England's free trade has prevented the law of increasing return from strengthening combinations of wealthy manufacturers against the general weal here to the same extent as it has in countries in which protection has prevailed, and notably America.

The problem of the relations between competition and combination is one in which differences of national character and conditions show themselves strongly. The Americans are the only great people whose industrial temper is at all like that of the English; and yet even theirs is not very like. Partly because of this difference of temper, but more because of the differences in the distribution of wealth and in the physical character of the two countries, the individual counts for much more in American than in English economic movements. Here, few of those who are very rich take a direct part in business; they generally seek safe investments for their capital; and again, among those engaged in business the middle class predominates, and most of them are more careful to keep what they have, than eager to increase it by risky courses. And lastly, tradition and experience are of more service and authority in an old country than in one which, like America, has not yet even taken stock of a great part of her natural resources, and especially those mineral resources, the sudden development of some of which has been the chief cause of many recent dislocations of industry.

In England, therefore, the dominant force is that of the average opinion of business-men; and the dominant form of association is that of the joint-stock company. But in America the dominant force is the restless energy and the versatile enterprise of a comparatively few very rich and able men, who rejoice in that power of doing great things by great means that their wealth gives them; and who have but partial respect for those who always keep their violins under glass cases. The methods of a joint-stock company are not always much to their mind; they prefer combinations that are more mobile, more elastic, more adventurous, and often more aggressive. For some

purposes they have to put up with a joint-stock company; but then they strive to dominate it, not be dominated by it. Again, since distances in America are large, many local monopolies are possible in America which are not possible in England; in fact, the area of a local monopoly there is often greater than that of the whole of England. A local coal combination, for instance, means quite a different thing there from what it does in England, and is more powerful every way.

Again, partly, but not solely, because they are so much in the hands of a few wealthy and daring men, railways, both collectively and individually, are a far greater power in America than in England. America is the home of the popular saying that, if the State does not keep a tight hand on the railways, the railways will keep a tight hand on the State; and many individual railways have, in spite of recent legislation, a power over the industries within their territories such as no English railway ever had: for the distances are great, and the all-liberating power of the free ocean befriends America little.

It is this change of area that is characteristic of the modern movement. In Adam Smith's time England was full of trade combinations, chiefly of an informal kind, indeed, and confined to very narrow areas; but very powerful within those areas, and very cruel. Even at the present day the cruellest of all combinations in England are, probably, in the trades that buy up small things, such as fish, and dairy and garden produce in detail, and sell them in retail; both producers and consumers being, from a business point of view, weak relatively to the intermediate dealers. But even in these trades there is a steady increase in the areas over which such combinations and partial monopolies extend themselves. New facilities of transport and communication tell so far on the side of the consumer, that they diminish the *intensity* of the pressure which a combination can exert; but, at the same time, they increase the *extension* of that pressure, partly by compelling, and partly by assisting, the combination to spread itself out more widely. And in England, as in other Western countries, more is heard every year of new and ambitious combinations; and of course many of them remain always secret.

But it is chiefly from America that a cry has been coming with constantly-increasing force for the last fifteen years or more, that in manufactures free competition favours the growth of large firms with large capitals and expensive plants; that such firms, if driven into a corner, will bid for custom at any sacrifice; that, rather than not sell their goods at all, they will sell them at the prime cost—that is, the actual outlay required for them, which is sometimes very little; that, when there is not enough work for all, these manufacturers will turn their bidding recklessly against one another, and will lower prices so far that the weaker of them will be killed out, and all of them injured; so that when trade revives they will be able, even without any combination among themselves, to put up prices to a high level; that these intense fluctuations injure both the public and the producers; and the producers being themselves comparatively few in number, are irresistibly drawn to some of those many kinds of combinations to which, nowadays, the name trust is commonly, though not quite accurately, applied; and that, in short, competition burns so furiously as to smother itself in its own smoke. It is a Committee of the American Congress that reports that "combination grows out of, and is the natural development of, competition, and that in many cases it is the only means left to the competitors to escape absolute ruin."

The subject is one on which it would be rash to speak confidently. We of this generation, being hurried along in a whirl of change, cannot measure accurately the forces at work, and it is probable that the best guesses we can make will move the smiles of future generations; they will wonder how we could have so much over-estimated the strength of some, and underestimated the strength of others. But my task is to try to explain what it is that economists of this generation are thinking about competition in relation to combination; and I must endeavour to reproduce their guesses, hazardous though this may be.

To begin with, I think that it is the better opinion that popular rumour, going now as ever to extremes, has exaggerated some features of the movement towards combination and monopoly, even in America. For instance, though it is said that there are a hundred commodities the sale of which in America is partly controlled by some sort of combination, many of these combinations turn out to be of small proportions, and others to be weak and loose. Again, the typical instances which are insisted on by those who desire to magnify the importance of the movement are nearly always the same, and they have all had special advantages of more or less importance.

This is specially true of the only trust which can show a long record of undisputed success on a large scale—the Standard Oil trust. For, firstly, the petroleum in which it deals comes from a few of Nature's storehouses, mostly in the same neighbourhood: and it has long been recognized that those who can get control over some of the richest natural sources of a rare commodity are well on their way towards a partial monopoly. And, secondly, the Standard Oil Trust has many of those advantages which have been long recognized as enabling large railway companies to get the better of their smaller neighbours; for, directly or indirectly, it has in some measure controlled the pipe lines and the railways which have carried its oil to the large towns and to tidal water.

On the other hand, we must remember that the future of a young and vigorous movement is to be measured, not so much by what it has achieved, as by what it has learnt; and that every unsuccessful attempt to hold together a trust has been a lesson as to what to avoid, taught to men who are wonderfully quick to learn. In particular, it is now recognized that a very large portion of the failures in the past have been due to attempts to charge too high a price; that this high price has tempted those on the inside to break faith, and has tempted those on the outside to start rival works, which may bleed the trust very much unless it consents to buy them up on favourable terms; and, lastly, that this high price irritates the public: and that, especially in some States, public indignation on such matters leads to rapid legislation that strikes straight at the offenders, with little care as to whether it appears to involve principles of jurisprudence which could not be applied logically and consistently without danger. The leaders in the movement towards forming trusts seem to be resolved to aim in the future at prices which will be not very tempting to any one who has not the economies which a large combination claims to derive, both in producing and in marketing, from its vast scale of business and its careful organization; and to be content with putting into their own pockets the equivalent of these economies in additition to low profits on their capital. There are many who believe that combinations of this kind, pursuing a moderate policy, will ultimately obtain so great a power as to be able to shape, in a great measure, the conditions of trade and industry.

It may be so, but these eulogists of trusts seem to claim for them both that individual vigour, elasticity, and originating force which belong to a number of separate firms, each retaining a true autonomy, and that strength and economy which belong to a unified and centralized administration. Sanguine claims of this kind are not new; they have played a great part in nearly all the bold schemes for industrial reorganization which have fascinated the world in one generation after another. But in this, their latest form, they have some special features of interest to the economic analyst.

They have a certain air of plausibility, for the organizers of trusts claim that they see their way to avoiding the weak points in ordinary forms of combination among traders, which consist in the fact that their agreements can generally be evaded without being broken. For instance, the most remarkable feature in the history of English railways during the present generation is, not their tendency to agree on the fares and freights to be charged over parallel lines—for that has long been a foregone conclusion—it is the marvellously effective competition for traffic which such railways have maintained, both of a legitimate kind, by means of improved conveniences offered to the public as a whole, or of an illegitimate kind, by means of those special privileges to particular traders which we are now, at last, seriously setting ourselves to stop by law.

It is difficulties of this kind which the modern movement towards trusts aims specially at overcoming. Trusts have very many forms and methods, but their chief motive in every case is to take away from the several firms in the combination all inducements to compete by indirect means with one another; and in every case the chief instrument for this purpose is some plan for pooling their aggregate receipts, and making the gains of each depend on the gains of all, rather than on the amount of business it gets for itself. But here the dilemma shows itself. If each establishment is left to its own devices, but has very little to lose by bad management, it is not likely long to remain well managed, and anyhow the trust does not gain much of the special economy resulting from production on a very large scale.

For this a partial remedy can sometimes be found in throwing as much of its work as possible on to those establishments which are best situated, have the best and most recent appliances and the ablest management, and, perhaps, closing entirely some of the others. But when once the pooling has begun, the combination is on an inclined plane, and every step hurries it on faster towards what is virtually complete amalgamation and consolidation. The recent history of trusts shows a constant tendency to give a more and more absolute power to the central executive and to reduce the heads of the separate establishments more and more nearly to the position of branch managers. In some cases the only substantial difference between such a trust and a consolidated joint-stock company is that it is nominally left open to the several parties contracting to claim their separate property after the lapse of a certain number of years, while some are already preparing to dissolve and reconstitute themselves formally as joint stock companies.

This tendency has been helped on by the action of the legislature and the law courts, and since this action can be traced back in some measure to the imperfect analysis of competition in the older economic writings, it has a special interest for us here. There seems to have been set up a false antithesis between competition and combination. For instance, if 100 workmen agreed to act together, as far as possible, in bargaining for the sale of their labour, they were denounced as combining to limit freedom, even when they did not interfere in any way with the liberty of other workmen, but merely deprived the employers of the freedom of making bargains with the 100 workmen, one by one. But the employer himself was allowed to unite in his own hands the power of hiring a hundred or twenty hundred men, and if he had not enough capital of his own he might take others into private, if not into public, partnership with him. Now, no trades union was likely to be as compact a combination, governed by as single a purpose, as a public or private firm, still less as an individual large employer; and therefore, there was not only a class injustice, but also a logical confusion, in prohibiting combinations among workmen, on the ground that free competition was a good, and that combination, being opposed to free competition, was, for that reason, an evil.

It was an additional grievance to the workmen that employers had all manner of facilities for combination, of which they made full use, as is vigorously urged by Adam Smith, to whom the working classes owe more than they know. And it was this social injustice, rather than the logical inconsistency of economists and legislators, that led workmen to claim—and for the greater part successfully—that nothing should be illegal if done by workmen in combination which would not be illegal if done by any one of them separately—a principle which works well practically in the particular case of workmen's combinations if applied with moderation; though it has no better claim to universal validity than the opposite doctrine.

But at present it is with the latter that we are concerned—the doctrine, namely, that a use of the rights of property which would be "combination in restraint of competition" if the ownership of the property were in many hands, is only a free use of the forms of competition when the property is all in a single hand. This doctrine has resulted in prohibitions of pooling between railways which were allowed to amalgamate, and in the prohibition of combination on the part of a group of traders to coerce others to act with them, or to drive others out of the trade, though all the while no attempt was made to hinder a single very wealthy firm from obtaining the despotic control of a market by similar means.

But to the economists of to-day the whole question appears both more complex and more important than it seemed to their predecessors, so they are inquiring in detail how far it is true that the looser forms of combination are specially dangerous in spite of their weakness, and even to some extent because of their weakness; how far the greater stability and publicity, and sense of responsibility and slowness of growth, of a single consolidated firm make it less likely to extend its operations over a very wide area, and less likely to make a flagrantly bad use of its power; and, lastly, how far it may be expedient to prohibit actions on the part of loose combinations, while similar actions on the part of individuals and private firms are allowed to pass in silence, because no prohibition against them could be effectual.

It is a sign of the times that the American Senate passed, on April 8 last, a Bill of Senator Sharman's, of which the second Section begins thus: "Every person who shall monopolise, or attempt to monopolise, or conspire with any other person or persons to monopolise, any part of the trade or commerce among the several States, or with foreign nations, shall be deemed guilty of a misdemeanour." This clause is interesting to the constitutional lawyer on account of the skill with which it avoids any interference by the central authority with the internal affairs of the separate States; and though, partly for this reason, it is perhaps intended to be the expression of a sentiment that may help to guide public opinion, rather than an enactment which will bear much direct fruit, yet it is of great interest to the economist as showing a tendency to extend to the action of individuals a form of public criticism which has hitherto been almost confined to the action of combinations.

To return, then, to the tendency of trusts towards consolidation. It is probable that the special legislative influences by which it has been promoted may be lessened, but that other causes will remain sufficiently strong to make a combination, which has once got so far as any sort of permanent pooling, tend almost irresistibly towards the more compact unity of a joint stock company. If this be so, the new movement will go more nearly on old lines than at one time seemed probable; and the question will still be the old one of the struggle for victory on the one hand between large firms and small firms, and on the other between departments of the Government, imperial or local, and private firms. I will then pass to consider the modern aspects of this question, ever old and ever new, but never more new and never more urgent than to-day.

To begin with, it is now universally recognized that there is a great increase in the number and importance of a class of industries, which are often called monopolies, but which are perhaps better described as *indivisible* industries. Such are the industries that supply gas or water in any given area, for only one such company in any district can be given leave to pull up the streets. Almost on the same footing are railways, tramways, electricity supply companies, and many others. Now, though there are some little differences of opinion among us as to the scale on which the owners of such undertakings when in private hands should be compensated for interference with what they had thought their vested rights, we are all agreed that such right of interference must be absolute, and the economists of today are eagerly inquiring what form it is most expedient for this interference to take. And here differences of opinion show themselves. The advantages of a bureaucratic government appeal strongly to some classes of minds, among whom are to be included many German economists and a few of the younger American economists who have been much under German influence. But those in whom the Anglo-Saxon spirit is strongest, would prefer that such undertakings, though always under public control, and sometimes even in public ownership, should whenever possible be worked and managed by private corporations. We (for I would here include myself) believe that bureaucratic management is less suitable for Anglo-Saxons than for other races who are more patient and more easily contented, more submissive and less full of initiative, who like to take things easily and to spread their work out rather thinly over long hours. An Englishman's or an American's life would involve too much strain to make them happy, while the Englishman would fret under the constraints and the small economies of their lives. Without therefore expressing any opinion as to the advantages of the public management of indivisible undertakings on the Continent, the greater part of the younger English and American economists are, I think, inclined to oppose it for England and America. We are not sure that we could exchange our own industrial virtues for those of the Continent if we wished to, and we are not sure that we do wish it. And though we recognize that the management of a vast undertaking by a public company has many of the characteristics of bureaucratic management, yet we think the former is distinctly the better suited for developing those faculties by which the Anglo-Saxon race has won its position in the world. We believe that a private company which stands to gain something by vigorous and efficient management by promptness in inventing, as well as in adopting and perfecting improvements in processes and organization, will do much more for progress than a public department.

Again, inferior as is a public company to a small private firm in its power and opportunities of finding out which among its employés have originating and constructive ability, a public department has much less still. And lastly it is more liable to have the efficiency of its management interfered with for the

purpose of enabling other persons to gain the votes of their constituents on questions in which it has no direct concern; and as a corollary from this, it tends to promote the growth of political immorality, and it suffers from that growth.

There is certainly a growing opinion among English and American economists that the State must keep a very tight hand on all industries in which competition is not an effective regulator; but this is the expression of a very different tone of thought from that which is leading so many German economists towards what is called State Socialism. In fact, so far as I can judge, English economists at all events are even more averse to State management than they were a few years ago; the set of their minds is rather towards inquiring how the advantages claimed for State management, without its chief evils, can be obtained even in what I have called indivisible industries; they are considering how a resolute intervention on the part of the State may best check the growth of *Imperia in Imperio*, and prevent private persons from obtaining an inordinate share of the gains arising from the development, through natural causes, of what are really semi-public concerns, at the same time that it leaves them sufficient freedom of initiative and sufficient security of gain by using that freedom energetically to develop what is most valuable in the energy and inventiveness of the Anglo-Saxon temper.[1]

But, though we dislike and fear the present tendency towards a widening of the area of public management of industries, we cannot ignore its actual strength. For more forethought and hard work are needed to arrange an effective public control over an undertaking than to put it bodily into the hands of a public department; and there is always a danger that in a time of hasty change the path of least resistance will be followed.

By way of illustration of the inquiries that have had their origin in this fear of public management, as contrasted with public control and public ownership, I would here mention a notion which has been suggested partly by the relations of some municipalities to their tramways, gas and water works. At present it is in a very crude form, and not ready for immediate application; but it seems to have occurred independently to a good many people, and it may have an important future. It is that a public authority may be able to own the franchise and, in some cases, part of the fixed capital of a semi-public undertaking, and to lease them for a limited number of years to a corporation who shall be bound to perform services, or deliver goods, at a certain price and subject to certain other regulations, some of which may perhaps concern their relations to their employés; and, further, that competition for the franchise shall turn on the price or the quality, or both, of the services or the goods, rather than the annual sum paid for the lease. Competition as to quality is, from the consumer's point of view, often just as beneficial as competition is to price, and sometimes more so. And in industries which obey the Law of Increasing Returns, as very many of these indivisible industries do, a reduction of price or an improvement of quality will confer on the consumer a benefit out of all proportion to the extra cost involved.[2]

But I have lingered too long over those industries which I have called indivisible, and I must pass to those in which competition exerts a pretty full sway. The first point to be observed is that competition in bargaining and competition in production stand in very different relations to the public interest; and that one of the great advances in modern analysis consists in the emphasis which it lays on the distinction between the two. Competition in bargaining constitutes a great part of competition in marketing, but is not the whole of it. For under marketing is included the whole of the effective organization of the trade side of a business; and most of this performs essential services for the public, and is, in fact, of the same order as production commonly so called. But a great part of marketing consists of bargaining, of manœuvring to get others to buy at a high price and sell at a low price, to obtain special concessions or to force a trade by offering them. This is, from the social point of view, almost pure waste; it is that part of trade as to which Aristotle's dictum is most nearly true, that no one can gain except at the loss of another. It has a great attraction for some minds that are not merely mean; but nevertheless it is the only part of honest trade competition that is entirely devoid of any ennobling or elevating feature. A claim is made on behalf of large firms and large combinations that their growth tends to diminish the waste, and on the whole perhaps it does. The one solid advantage which the public gain from a combination powerful enough to possess a local monopoly is that it escapes much waste on advertising and petty bargaining and manœuvring. But its weakness in this regard lies in the fact that to keep its monopoly it must be always bargaining and manœuvring on a large scale. And if its monopoly is invaded, it must bargain and manœuvre widely in matters of detail as well as in larger affairs.

Still less can we fully concede, without further proof, the claim which has been urged on behalf of such combinations, that they will render industry more stable and diminish the fluctuations of commercial activity. This claim, though put forward confidently and by many writers, does not appear to be supported by any arguments that will bear examination. On the one hand some industries which are already aggregated into large and powerful units, such as railway companies, give exceptionally steady employment; and others, such as the heavy iron and the chemical industries, exceptionally unsteady. And when combinations succeed in steadying their own trades a very little, they often do it by means which diminish production and disturb other trades a very great deal. The teaching of history seems to throw but little light on the question, because the methods of regulation which are now suggested have not much in common with those of earlier times, while the causes which govern variations in prices have changed their character completely.

Let us then next turn to the economies of production on a large scale. They have long been well known, and our forefathers certainly did not underrate their importance. For, though the absence of any proper industrial census in England prevents us from getting exact information on the subject, yet there seems no doubt that the increase in the average size of factories has gone on, not faster, but slower than was thought probable a generation or two ago. In many industries, of which the textile may be taken as a type, it has been found that a comparatively small capital will command all the economies that can be gained by production on a large scale; and it seems probable that in many industries in which the average size of businesses has been recently increasing fast, a similar position of maximum economy will shortly be attained without any much further increase in size.

Those reductions in the expenses of production of commodities which have been claimed by the eulogists of trusts and other large combinations, as tending to show that their gains are not at the expense of the public, turn out generally to have been at least equalled by the reductions in the expenses of production in similar industries in which there was no combination. And this count in their eulogy, though it may truly stand for something, seems to have been much exaggerated.

After all, what these very large public firms and combinations of firms have done has generally been only to turn to good account existing knowledge, and not to increase that knowledge. And this brings us to the main reason for regarding with some uneasiness any tendency there may be towards such consolidations of business. Observation seems to show, what might have been anticipated *à priori*, that though far superior to public departments, they are, in proportion to their size, no less inferior to private businesses of a moderate size in that energy and resource, that restlessness and inventive power, which lead to the striking out of new paths. And the benefits which the world reaps from this originality are apt to be underrated. For they do not come all at once like those gains which a large business reaps by utilizing existing knowledge and well-proven economies; but they are cumulative, and not easily reckoned up. He who strikes out a new path by which the work of eight men is rendered as efficient as that of ten used to be, in an industry that employs 100,000 men, confers on the world a benefit equal to the labour of 20,000 men. And this benefit may in many cases be taken as running for many years. For though his discovery might have been made later by some one else of equal inventive power, yet this some one else, starting with that discovery in hand, is likely to make another improvement on it.

[1] Among the younger English economists who have written on the subject of combinations, trusts, and Government interference, I would specially refer to Mr. Rae and Prof. Foxwell. Most of the other young American economists have written on it instructively from various points of view, and in Mr. Baker's "Monopolies and the People," to which I am myself much indebted, the English reader will find condensed into a short compass an account of the general position of these questions in America, together with some bold and interesting suggestions for reform. Some useful documents relating to trusts have recently been published in a Consular Report by our Foreign Office [5896–32].

[2] This belongs to a class of questions relating to monopolies, &c., the more general and abstract aspects of which can be best shown by the diagrammatic method.

I believe that the importance of considerations of this kind is habitually underrated in the world at large; and that the older economists, though fully conscious of them, did not explain with sufficient clearness and iteration the important place which they take in the claims of industrial competition on the gratitude of mankind.

The chemist in his laboratory can make experiments on his own responsibility: if he had to ask leave from others at each step he would go but slowly, and though the officials of a company may have some freedom to make experiments in detail, yet even as regards these they seldom have a strong incentive to exertion; and in great matters the freedom of experimenting lies only with those who undertake the responsibility of the business.

It may indeed be admitted that some kinds of industrial improvements are getting to depend on the general increase of scientific knowledge rather than on such experiments as can only be made by business men. And this, which is an important fact so far as it goes, may be used as a convenient introduction to the next point that I want to make in the analysis of competition. It is that the motives which induce business men to compete for wealth are not altogether as sordid as the world in general, and I am forced to admit, economists in particular have been wont to assume.

The chemist or the physicist may happen to make money by his inventions, but that is seldom the chief motive of his work. He wants to earn somehow the means of a cultured life for himself and his family, but, that being once provided, he spends himself in seeking knowledge partly for its own sake, partly for the good that it may do to others, and last, and often not least, for the honour it may do himself. His discoveries become collective property as soon as they are made, and altogether he would not be a very bad citizen of Utopia just as he is. For it would be a great mistake to suppose that the constructors of Utopias from the time of Plato downwards have proposed to abolish competition. On the contrary, they have always taken for granted that a desire to do good for its own sake will need to be supplemented by emulation or competition for the approbation of others.

But business men are very much of the same nature as scientific men; they have the same "instincts of the chase," and many of them have the same power of being stimulated to great and even feverish exertions by emulations that are not sordid or ignoble. This part of their nature has however been confused with and thrown into the shade by their desire to make money. The chief reason why the scientific man does not care much for money is that in scientific work the earning of much money is no proof of excellence, but sometimes rather the reverse. On the other hand, in business a man's money-earning power, though not an accurate test of the real value to the world of what he has done, is yet often the best available. It is that test which most of those, for whose opinion he cares, believe to be more trustworthy than the highly-coloured reports the world hears from time to time of the benefits which it is just going to derive from a new invention or plan of organizing that is just going to revolutionize a branch of industry. And so all the best business men want to get money, but many of them do not care about it much for its own sake; they want it chiefly as the most convincing proof to themselves and others that they have succeeded.

These are the very men for whom the older economists were most eager to claim freedom of competition as needful to evoke them to do fully their high work for the world. But they seem to have made the error of running together and treating as though they were one, two different positions.

The first is that industrial progress depends on our getting the right men into the right places and giving them a free hand, and sufficient incitement to exert themselves to the utmost. And the second position is that nothing less than the enormous fortunes which successful men now make and retain would suffice for that purpose. This last position seems to be untenable.

The present extreme inequalities of wealth tend in many ways to prevent human faculties from being turned to their best account. A good and varied education, freely prolonged to those children of the working classes who showed the power and the will to use it well, an abundance of open-air recreation even in large towns, and other requisites of a wholesome life—such things as these might, most of us are inclined to think, be supplied by taxes levied on the rich, without seriously checking the accumulation of material capital; and with the effect of increasing rather than diminishing the services which competition renders to society by tending to put the ablest men into the most important posts, the next ablest into the next most important, and so on, and by giving to those in each grade freedom sufficient or the full exercise of their faculties.

It is quite true that where any class of workers have less than the necessaries for efficiency, an increase of income acts directly on their power of work. But when they already have those necessaries, the gain to production from a further increase of their income depends chiefly on the addition that it makes, not to their power of working, but to their will to exert themselves. And all history shows that a man will exert himself nearly as much to secure a small rise in income as a large one, provided he knows beforehand what he stands to gain, and is in no fear of having the expected fruits of his exertions taken away from him by arbitrary spoliation. If there were any fear of that he would not do his best; but if the conditions of the country were such that a moderate income gave as good a social position as a large one does now; if to have earned a moderate income were a strong presumptive proof that a man had surpassed able rivals in the attempt to do a difficult thing well, then the hope of earning such an income would offer to all but the most sordid natures, inducements almost as strong as they are now when there is an equal hope of earning a large one.

On all this class of questions modern economists are inclined to go a little way with the socialists. But all socialist schemes, and especially those which are directly or indirectly of German origin, seem to be vitiated by want of attention to the analysis which the economists of the modern age have made of the functions of the undertaker of business enterprises. They seem to think too much of competition as the exploiting of labour by capital, of the poor by the wealthy, and too little of it as the constant experiment by the ablest men for their several tasks, each trying to discover a new way in which to attain some important end. They still retain the language of the older economists, in which the employer, or undertaker, and the capitalist are spoken of, as though they were, for all practical purposes, the same people. The organ of the German school of English socialists prints frequently in thick type the question, "Is there one single useful or necessary duty performed by the capitalist to-day which the people organized could not perform for themselves?" It would be just as reasonable to ask if there is a single victory to which Julius Cæsar or Napoleon conducted their troops, which the troops properly organized could not have equally well won for themselves; or whether there is a single thing written by Shakespeare which could not have been equally well written by any one else who, as Charles Lamb said, happened to "have the mind to do it." It is quite true that many business men earn large incomes by routine work. It is just in these cases that Co-operation can dispense with middlemen and even employers. But the German socialists have been bitter foes of Co-operation; though this antagonism is less than it was.

The world owes much to the socialists, as it does to every set of enthusiasts among whom there are honest men; and many a generous heart has been made more generous by reading their poetic aspirations. But before their writings can be regarded as serious contributions to economic science, they must make more careful and exact analysis of the good and the evil of competition; and they must suggest some reasonably efficient substitute for that freedom which our present system offers to constructive genius to work its way to the light, and to prove its existence by attempting difficult tasks on its own responsibility, and succeeding in them. For those who have done most for the world have seldom been those whom their neighbours would have picked out as likely for the work. They must not, as even Mr. Bellamy and other American socialists do, in spite of their strong protestations to the contrary, assume implicitly a complete change of human nature; and propound schemes which would much diminish the aggregate production, but which they represent as enabling every family to attain an amount of material well-being which would be out of reach of the aggregate income if England or America were divided out equally among the population.

But though the socialists have ascribed to the virtues inherent in the human breast, and to the regulating force of public opinion, a much greater capacity for doing the energizing work of competition than they seem really to have; yet, unquestionably, the economists of to-day do go beyond those of earlier generations in believing that the desire of men for the approval of their own conscience, and the esteem of others, is an economic force of the first order of importance, and that its strength is steadily increasing with the increase and the diffusion of knowledge, and

with the constant tendency of what had been regarded as private and personal issues to become public and national.

Public opinion acts partly through the Government. The enforcement of the law in economic matters occupies the time of a rapidly increasing number of people; and though its administration is improving in every way, it fails to keep pace with the demands resulting from the growing complexity of economic organization, and the growing sense of responsibility of public opinion. A part of this failure is due to a cause which might easily be remedied; it is that the adjustment of punishment to offences is governed by traditions descending from a time when the economic structure of England was entirely different. This is most conspicuous with regard to the subtler, or, as they are sometimes called with unconscious irony, the more gentlemanly forms of commercial fraud on a large scale; for which the punishment awarded by the law courts is often trivial in comparison with the aggregate gains which the breakers of the law, whose offences can seldom be proved, make by their wrongdoing; and it is still more trivial in comparison with the aggregate injury which such wrongdoing inflicts on the public. Many of the worst evils in modern forms of competition could be diminished by merely bringing that part of the law which relates to economic problems of modern growth into harmony with that which relates to the old-fashioned and well-matured economic questions relating to common picking and stealing. And somewhat similar remarks apply to the punishments for infringements of the Factory Acts.

But at best the action of the law must be slow, cumbrous, and inelastic, and therefore ineffective. And there are many matters in which public opinion can exercise its influence more quickly and effectively by a direct route, than by the indirect route of first altering the law. For of all the great changes which our own age has seen in the relative proportions of different economic forces, there is none so important as the increase in the area from which public opinion collects itself, and in the force with which it bears directly upon economic issues.

For instance, combinations of labour on the one side, and of employers on the other, are now able to arrange plans of campaign for whole trades, for whole counties, for the whole country, and sometimes even beyond. And partly on account of the magnitude of the interests concerned, partly because trade disputes are being reduced to system, affairs which would be only of local interest are discussed over the whole kingdom.

The many turbulent little quarrels which centred more often about questions of individual temper than of broad policy, are now displaced by a few great strikes, as to which public opinion is on the alert; so that a display of temper is a tactical blunder. Each side strives to put itself right with the public; and requires of its leaders above all things that they should persuade the average man that their demands are reasonable, and that the quarrel is caused by the refusal of the other side to accept a reasonable compromise.

This change is increasing the wisdom and the strength of each side; but the employers have always had fairly good means of communication with one another; it is the employed that have gained most from cheap means of communication by press, by railway, and by telegraph, and from improvements in their education and in their incomes, which enable them to make more use of these new and cheaper facilities. And while the employers have always known how to present their case to the public well, and have always had a sympathetic public, the working classes are only now beginning to read newspapers enough to supply an effective national working class opinion, and they are only now learning how to present their case well, and to hope much from, or care much for, the opinion of those who are neither employers nor of the working classes.

I myself believe that in all this the good largely predominates over the evil. But that is not the question with which I am specially concerned at present. My point is that, in the scientific problem of estimating the forces by which wages are adjusted, a larger place has to be allowed now than formerly to the power of combination, and to the power of public opinion in judging, and criticizing, and aiding that combination; and that all these changes tend to strengthen the side of the employés, and to help them to get a substantial though not a great increase of real wages; which they may, if they will, so use as to increase their efficiency, and therefore to increase still further the wages which they are capable of earning, whether acting in combination or not.

And thus public opinion has a very responsible task. I have spoken of it as the opinion of the average man; and he is very busy, and has many things to think about. He makes great mistakes, but he learns by all of them. He has often astonished the learned by the amount of ignorance and false reasoning which he can crowd into the discussion of a difficult question; and still more by the way in which he is found at last to have been very much in the right on the main issue. He is getting increased power of forming a good and helpful opinion, and he is being educated in mind and in spirit by forming it, and by giving it effect. But in the task which he is undertaking there are great difficulties ahead.

In an industrial conflict each side cares for the opinion of the public at large, but especially for that of those whose sympathy they are most likely to get: in the late South Wales strike, for instance, the railway companies were specially anxious about the good opinion of the shippers, and the engine drivers about that of the colliers. And there is some fear that when party discipline becomes better organized, those on either side will again get to care less for any public opinion save that of their own side. And if so, there may be no great tendency towards agreement between the two sides as to what are reasonable demands.

It is true that there is always the action of outside competition tending to visit with penalties either side, which makes excessive use of any tactical advantage it may have obtained. As we have just noticed, the shrewdest organizers of a trust are averse to raising the price of its wares much above the normal or steady competition price. And the first point which courts of conciliation and arbitration have to consider is, what are the rates of wages on the one hand and of profits on the other, which are required to call forth normal supplies of labour and capital respectively; and only when that has been done, can an inquiry be properly made as to the shares in which the two should divide between them the piece of good or ill fortune which has come to the trade. Thus the growth of combinations and partial monopolies has in many ways increased, and in no way diminished, the practical importance of the careful study of the influences which the normal forces of competition exert on normal value.

But it must be admitted that the direct force of outside competition in some classes of wages disputes is diminishing; and though its indirect force is being increased by the increased power which modern knowledge gives us of substituting one means of attaining our ends for another, yet on the whole the difficulty of deciding what is a reasonable demand is becoming greater. The principles on which not only the average man, but also an expert court of conciliation or arbitration should proceed in forming their judgment, are becoming, in spite of the great increase of knowledge, more and more vague and uncertain in several respects.

And there are signs of a new difficulty. Hitherto the general public has been enlightened, and its interests protected by the fact that the employers and employed when in conflict have each desired to enlighten the public as to the real questions at issue; and the information given on one side has supplemented and corrected that on the other: they have seldom worked together systematically to sacrifice the interests of the public to their own, by lessening the supply of their services or goods, and thus raising their price artificially. But there are signs of a desire to arrange firm compacts between combinations of employers on the one side and of employés on the other to restrict production. Such compacts may become a grievous danger to the public in those trades in which there is little effective competition from foreign producers: a danger so great that if these compacts cannot be bent by public opinion they may have to be broken up by public force.

It is, therefore, a matter of pressing urgency that public opinion should accustom itself to deal with such questions, and be prepared to throw its weight against such compacts as are injurious to the public weal, that is, against such compacts as are likely to inflict on the public a real loss much greater than the gain to that trade; or in other words, are of such a nature that if their principle were generally adopted in all trades and professions, then all trades and professions would lose as buyers more than they would gain as sellers.

I must now close this imperfect and fragmentary study. I have endeavoured to give some illustrations of the changes which are coming over economic studies. I believe that the great body of modern economists think that the need of analysis and general reasoning in economics is not less than our predecessors supposed, but more. And this is because we think economic problems

more difficult than they did. We are recognizing more clearly than they did that all economic studies must have reference to the conditions of a particular country and time. Economic movements tend to go faster than ever before, but, as Knies pointed out, they tend also to synchronize; and the economists of our western countries have much more to learn now than fifty years ago from the contemporary history of other countries; but in spite of the many great benefits which we are deriving from the increase of our historical knowledge, the present age can rely less than any other on the experience of its predecessors for aid in solving its own problems.

Every year economic problems become more complex; every year the necessity of studying them from many different points of view and in many different connections becomes more urgent. Every year it is more manifest that we need to have more knowledge and to get it soon in order to escape, on the one hand, from the cruelty and waste of irresponsible competition and the licentious use of wealth, and on the other from the tyranny and the spiritual death of an ironbound socialism.

SECTION G.

MECHANICAL SCIENCE.

OPENING ADDRESS BY CAPTAIN NOBLE, C.B., F.R.S., F.R.A.S., F.C.S., M.INST.C.E., PRESIDENT OF THE SECTION.

IN taking over the chair of this Section from my distinguished predecessor, I cannot but feel myself to some extent an intruder into the domain of mechanical science, and I am conscious that the office which I have the honour to hold would have been more worthily filled by one of the great mechanicians who have won for the town in which we hold our meeting so widespread a reputation.

I can truly say the claims on my time are so considerable that I should not have ventured to appear before you in the character of President of this Section had it not been for my desire to afford what little support might be in my power to my friend the President of the British Association, with whom for so long a period I have been associated by so many ties.

I believe I should have consulted best both my own feelings and your patience by merely opening the Section in a formal manner, and proceeding at once to the business of the meeting. One of my predecessors, however, has pointed out that Sir F. Bramwell, whose authority is too great to be disputed, has ruled that to depart from the time-honoured practice of an address is an act of disrespect to the Section—a ruling which has, without cavil, been accepted.

I therefore propose to direct your attention, by a few brief remarks, to that branch of mechanical science with which I am best acquainted. I shall endeavour to show the great indebtedness of the naval and military services to mechanical science during the period with which I have been more or less connected with them, and the complete revolution which has in consequence resulted in every department and in every detail.

But before commencing with my special subject, it is impossible that I should pass over in silence the great work which has excited so much interest in the engineering world, and which, since we last met, has, with formalities worthy of the occasion, been opened by H.R.H. the Prince of Wales.

It is in no way detracting from the merit of the distinguished engineers who have with so much boldness in design, with such an infinity of care in execution, with so much foresight in every detail, given to the country this great monument of skill, if I venture to point out that, without the great advance of mechanical and metallurgical science during the present generation, and the co-operation of a host of workers, a creation like that of the Forth Bridge would have been an impossibility.

The bridge has been so frequently and so fully described that it is unnecessary in this address I should do more than draw your attention to some of its main features.

The bridge, with its approach-viaducts, has a total length of 8296 feet, or nearly a mile and six-tenths; and this length comprises two spans of 1710 feet, two of 680½ feet, fifteen of 160 feet, four of 57 feet, and three of 25 feet.

The deepest foundation is 90 feet below high-water mark, and the extreme height of the central position of the cantilever is 361 feet above the same datum, making the extreme total height of the bridge 451 feet.

The actual minimum headway in the channels below the centre of the main spans at high-water spring tides is a little over 150 feet, and the rail level is about 6 feet higher.

The weight of steel, nearly all riveted work, is 54,076 tons, and the amount of masonry and concrete 4,057,555 cubic feet.

It is difficult, even for experts, fully to appreciate the stupendous amount of work indicated by these figures. During the Paris Exhibition the Eiffel Tower justly excited considerable admiration, and brought its designer into much repute; but that great work sinks altogether into insignificance when compared with the Forth Bridge.

Conceive, as I have heard described, the Eiffel Tower built, not vertically, but horizontally; conceive it further built without support, and at a giddy height over an arm of the sea. Such a work would do little more than reach half across one of the main spans of this great bridge.

Those only who have had work of a similar nature can fully appreciate the innumerable experiments that must have been made, and the calculations that must have been gone through to secure the maximum attainable rigidity both with respect to the strains induced vertically by the railway traffic and its own weight, and horizontally by the force of gales.

The anxiety as to the security of the erection might well daunt the most skilful engineer. We are told that, apart from the permanent work, many hundreds of tons of weight in the shape of cranes, temporary girders, winches, steam boilers, rivet furnaces, and riveting machines, miles of steel-wire rope, and acres of timber staging were suspended from the cantilevers. A heavy shower of rain would in a few minutes give an additional weight of about 100 tons; and in their unfinished state, while approaching completion, the force of any gale had to be endured.

I trust that, as the Forth Bridge has been a great engineering, it may likewise prove a financial success, and I feel sure that all who hear me are rejoiced that it has pleased Her Majesty to confer the distinguished honours she has awarded to Sir John Fowler and Sir B. Baker—honours, I may add, that have rarely been more worthily bestowed.

Let me turn now to the subject on which I propose to address you; and I shall first advert to the change which within my own recollection has taken place in that service which has been the pride and glory of the country in time past, and on which we must rely in the future as our first and principal means at once of defence and attack.

To give even an idea of the revolution which our navy has undergone, I must refer in the first instance to the navy of the past. I must refer to those vessels which in the hands of our great naval commanders won for England victories which left her at the close of the great wars supreme upon the sea.

A "first-rate" of those days (I will take the *Victory* as a type) was a three-decker 186 feet in length, 52 feet in breadth, with a displacement of 3500 tons, and she carried an armament of 102 guns, consisting of thirty 42- and 32-pounders, thirty 24-pounders, forty 12-pounders, and two 68-pounder carronades (the heaviest of her guns was a 42-pounder), and she had a complement of nearly 900 men. When we look at the wonderful mechanism connected with the armaments of the fighting-ships of the present day, it is difficult to conceive how such feats were accomplished with such rude weapons.

With the exception of a few small brass guns, the guns were mere blocks of cast iron, the sole machining to which they were subjected consisting in the formation of the bore and the drilling of the vent.

A large proportion of nearly every armament consisted of carronades—a piece which was in those days in great favour. They threw a shot of large diameter from a light gun with a low charge, and their popularity was chiefly due to the rapidity with which they could be worked. The great object of every English commander was, if it were possible, to bring his ship alongside that of the enemy; and under these circumstances the low velocity given by the carronades became of comparatively small moment, while the ease of working and the large diameter of the shot were factors of the first importance.

The carriages on which the rude weapons I have described were placed were themselves, if possible, even more rude. They were of wood, and consisted of two cheeks with recesses for the trunnions, which were secured by cap squares, the cheeks being connected by transoms, and the whole carried by trucks. The gun was attached to the vessel's side, and the recoil controlled by breeching. The elevation was fixed by quoins which rested

on a quoin bed, and handspikes were used either for elevating or for training.

It is obvious that, to work smartly so rude a machine, a very strong gun's crew was required. Indeed, the gun and its carriage were literally surrounded by its crew, and I may refer those who desire to acquaint themselves with the general arrangements of what was once the most perfect fighting-machine of the first navy in the world, to the frontispiece of a book now nearly forgotten—I mean Sir Howard Douglas's "Naval Gunnery."

The mechanical appliances on board these famed war-vessels of the past were of the simplest possible form, and such as admitted of rapid renewal or repair. There was no source of power except manual labour; but, when handled with the unrivalled skill of British seamen, the handiness of these vessels, and the precision with which they were manœuvred, was a source of never-ending admiration.

Those who have seen, as I have done, a fleet like the Mediterranean squadron enter a harbour, such as Malta, under full sail, and have noted the precision with which each floating castle moved to her appointed place, the rapidity with which her canvas was stowed, have seen a sight which I consider as the most striking I have witnessed, and infinitely more imposing than that presented under like circumstances by modern vessels, any one of which could in a few minutes blow out of the water half a dozen such men-of-war as I have been just describing.

I must not, however, omit to mention two advantages possessed by the old type of war-vessels, which, if we could reproduce them, would greatly please modern economists. I mean, their comparatively small cost, and the length of time the vessels remained fit for service.

When the *Victory* fought the battle of Trafalgar she had been afloat for forty years, and her total cost, complete with her armament and all stores, was probably considerably under £100,000. The cost of a first-rate of the present day, similarly complete, would be nearly ten times as great.

The most improved battle-ships of the period just anterior to the Crimean war differed from the type I have just described, mainly by the addition of steam power, and for the construction of these engines the country was indebted to the great pioneers of marine engineering, such as J. Penn and Sons, Maudslay Sons and Field, Ravenhill, Miller, and Co., Rennie Bros., &c., not forgetting Messrs. Humphreys and Tennant, whose reputation and achievements now are even more brilliant than in these earlier days.

Taking the *Duke of Wellington*, completed in 1853, as the type of a first-rate just before the Crimean war, her length was 240 feet, her breadth 60 feet, her displacement 5830 tons, her indicated horse-power 1999, and her speed on the measured mile 9·89 knots. Her armament consisted of 131 guns, of which thirty-six 8-inch and 32-pounders were mounted on the lower deck, a similar number on the middle deck, thirty-eight 32-pounders on the main deck, and twenty short 32-pounders and one 68-pounder pivot gun on the upper deck.

Taking the *Cæsar* and the *Hogue* as types of second- and third-rate line-of-battle ships, the former, which had nearly the displacement of the *Victory*, had a length of 207 feet, a breadth of 56 feet, and a mean draught of 21. She had 1420 indicated horse-power, and her speed on the measured mile was 10·3 knots. Her armament consisted of twenty-eight 8-inch guns and sixty-two 32-pounders, carried on her lower, main, and upper decks. The *Hogue* had a length of 184 feet, a breadth of 48 feet 4 inches, a mean draught of 22 feet 6 inches: she had 797 indicated horse-power, and a speed of 8½ knots. Her armament consisted of two 68-pounders of 95 cwt., four 10-inch guns, twenty-six 8-inch guns, and twenty-eight 32-pounders of 56 cwt.—sixty guns in all.

Vessels of lower rates (I refer to the screw steam frigates of the period just anterior to the Crimean war) were, both in construction and armament, so closely analogous to the line-of-battle-ships that I will not fatigue you by describing them, and will only allude to one other class, that of the paddle-wheel steam frigate, of which I may take the *Terrible* as a type. This vessel had a length of 226 feet, a breadth of 43 feet, a displacement of about 3000 tons, and an indicated horse-power of 1950. Her armament consisted of seven 68-pounders of 95 cwt., four 10-inch guns, ten 8-inch guns, and four light 32-pounders.

It will be observed that in these armaments there has been a very considerable increase in the weight of the guns carried. As I have said, the heaviest guns carried by the *Victory* were the 42-pounders of 75 cwt., but in these later armaments the 68-pounder of 95 cwt. is in common use, and you will have noted that the carronades have altogether disappeared. But as regards improvements in guns or mounting, if we except the pivot-guns, with respect to which there was some faint approach to mechanical contrivance to facilitate working, the guns and carriages were of the rude description to which I have alluded.

In one respect, indeed, a great change had been made. Shell-fire had been brought to a considerable state of perfection, and the importance ascribed to it may be traced in the number of 10-inch and 8-inch shell-guns which entered into the armament of the *Duke of Wellington* and the other ships I have mentioned. Moorsom's concussion fuse and other similar contrivances lent great assistance to this mode of warfare, and its power was soon terribly emphasized by the total destruction of the Turkish squadron at Sinope by the Russian fleet. In that action, shell-fire appears to have been almost exclusively used, the Russians firing their shell with rather long-time fuses in preference to concussion, with the avowed object of there being time before bursting to set fire to the ship in which they lodged.

It is curious to note in the bygone discussions relative to shell-fire the arguments which were used against it; among others it was said that the shell would be more dangerous to those who used them than to their enemies. There was some ground for this contention, as several serious catastrophes resulted from the first attempts to use fused shells. Perhaps the most serious was that which occurred on board H.M.S. *Theseus*, when seventy 36- and 24-pounder shells captured from a French storeship and placed on the quarter-deck for examination exploded in quick succession, one of the fuses having by some accident been ignited. The ship was instantly in flames; the whole of the poop and after-part of the quarter-deck were blown to pieces. The vessel herself was saved from destruction with the greatest difficulty, and forty-four men were killed and forty-two wounded.

This accident was due to a neglect of obvious precautions, which would hardly occur nowadays, but I have alluded to the circumstance because the same arguments, or arguments tending in the same direction, are in the present day reproduced against the use of high explosives as bursting charges for shells. To this subject I myself and my friend and fellow labourer, Mr. Vavasseur, have given a good deal of attention, and the question of the use of these shells and the best form of explosive to be employed with them is, I believe, receiving attention from the Government. The importance of the problem is not likely to be overrated by those who have witnessed the destruction caused by the bursting of a high explosive shell, and who appreciate the changes that by their use may be rendered necessary, not only in the armaments, but even in important constructional points of our men-of-war.

Shortly before the termination of the long period of peace which commenced in 1815, the attention of engineers and those conversant with mechanical and metallurgical science, seems to have been strongly directed towards improvements in war material. It may easily be that the introduction of steam into the navy may have had something to do with the beginning of this movement, but its further progress was undoubtedly greatly accelerated by the interest in the subject awakened by the disturbance of European peace which commenced in 1854.

Since that date—whether we have regard to our vessels of war, the guns with which they and our fortresses are armed, the carriages upon which those guns are mounted, or the ammunition they employ—we shall find that changes so great and so important have been made that they amount to a complete revolution. I believe it would be more correct to say several complete revolutions. It is at least certain that the changes which were made within the period of ten years following 1854, were far more important and wide-spreading in their character than were all the improvements made during the whole of the great wars of the last and the commencement of the present century.

Indeed, it has always struck me as most remarkable that during the long period of the Napoleonic and earlier wars, when the mind of this country must have been to so large an extent fixed on everything connected with our naval and military services, so little real progress was made.

Our ships, no doubt, were the best of their class, although, I believe, we were indebted for many of our most renowned models to vessels captured from our neighbours. They were fitted for sea with all the resources and skill of the first seamen of the world, and when at sea were handled in a manner to command universal admiration. But their armaments were of

the rude nature I have described, and so far as I can see possessed little, if any, advantage over those of nearly a couple of centuries earlier. It is not improbable that the great success which attended our arms at sea may have contributed to this stagnation.

The men who with such arms achieved such triumphs, may well be forgiven for believing that further improvement was unnecessary, and it must be remembered that the practice of engaging at very close quarters minimised to a great extent the most striking deficiencies of the guns and their mountings.

I need scarcely, however, remind you that were two vessels of the old type to meet, one armed with her ancient armament, the other with modern guns, it would be vain for the former to attempt to close. She would be annihilated long before she approached sufficiently near to her antagonist to permit her guns to be used with any effect.

It would be quite impossible, within reasonable limits of time, to attempt to give anything like an historical account of the changes which have taken place in our ships of war during the last thirty-five years, and the long battle between plates and guns will be fresh in the memory of most of us. The modifications which the victory of one or the other impressed on our naval constructions are sufficiently indicated by the rapid changes of type in our battle-ships, and by the number of armour-clads once considered so formidable, but seldom now mentioned except to adorn the tale of their inutility. The subject also requires very special knowledge, and to be properly handled must be dealt with by some master of the art, such as our Director of Naval Construction.

Let me now compare with the vessels of the past those of the present day, and for my purpose I shall select for comparison as first-rates the *Victoria* and the *Trafalgar*. The *Victoria* has a length of 340 feet, a breadth of 70 feet; she has a displacement of about 10,500 tons, an indicated horse-power of 14,244, and she attained a speed on the measured mile of 17½ knots; she has a thickness of 18 inches of compound armour on her turrets, a similar thickness protects the redoubt, and her battery-deck is defended with 3-inch plates. Her armament consists of two 16¼-inch 110-ton guns, one 10-inch 30 ton gun, twelve 6-inch 5-ton guns, twelve 6-pounder and nine 3-pounder quick-firing guns, two machine guns, and six torpedo guns.

The *Trafalgar* has a length of 345 feet, or very nearly double the length of the *Victory*, a displacement of 12,000 tons, an indicated horse-power of 12,820, and a speed on the measured mile of a little over 17¼ knots. Her armament consists of four 68-ton guns, six 4·7-inch quick-firing guns, six 6 pounder, and nine 3-pounder quick-firing guns, six machine and six torpedo-guns.

Comparing the armament of the *Victoria* with that of the *Victory*, we find, to quote the words of Lord Armstrong—which when evaluating the progress we have made will bear repetition—that while the heaviest gun on board the *Victory* was a little over 3 tons, the heaviest on board the *Victoria* is a little over 110 tons. The largest charge used on board the *Victory* was 10 lbs., the largest on board the *Victoria* close on 1000 lbs.; the heaviest shot used in the *Victory* was 68 lbs., in the *Victoria* it is 1800 lbs. The weight of metal discharged from the broadside of the *Victory* was 1150 lbs., from that of the *Victoria* it is 4750 lbs. But having regard to the energy of the broadside, the power of each ship is better indicated by the quantity of powder expended than by the weight of metal discharged, and while the broadside fire from the *Victory* consumed only 355 lbs. of powder, that from the *Victoria* consumes 3120 lbs.

These figures show in the most marked manner the enormous advances that have in every direction been made in the construction and armament of these marine monsters; but it is when we come to the machinery involved in our first-rates that the contrast between the past and the present is brought most strongly into prominence.

I have alluded to the simplicity of the arrangements on board the old battle-ships, but no charge of this nature can be made against the present. The *Victoria* has no less than twenty-four auxiliary steam-engines in connection with her main engines, viz. two starting, two running, eight feed, eight fan, for forced draught, and four circulating water engines. She has in addition thirty steam engines unconnected with her propelling engines, viz. six fire and bilge engines, two auxiliary circulating engines, four fan engines for ventilating purposes, two fresh-water pumping engines, two evaporating fuel engines, one workshop, one capstan, and five electric-light engines, four air-compressing and three pumping engines for hydraulic purposes.

She has further thirty-two hydraulic engines, including two steering engines, four ash hoisting engines, two boat engines, four ammunition lifts, two turret-turning engines, one topping winch, two transporting and lifting engines, two hydraulic bollards, and fourteen other engines for performing the various operations necessary for the working of her heavy guns, making a grand total of eighty-eight engines. This number is exclusive of the machinery in the torpedo and other steam-boats, and of the locomotive engines in the torpedoes carried, which are themselves engines of a most refined and delicate character.

At an earlier point in my address I alluded to the incomparable seamanship of our bygone naval officers. Seamanship will, I fear, in future naval battles no longer play the conspicuous part it has done in times past. The weather-gage will belong not to the ablest sailor, but to the best engineer and fastest vessel, but the qualities of pluck, energy, and devotion to their profession which distinguished the seamen of the past have, I am well assured, been transmitted to their descendants, and I am glad to have the opportunity of expressing my admiration of the ability and zeal with which the naval officers of the present day have mastered, and the skill with which they use, the various complicated, and in some cases delicate machinery which mechanical engineers have placed in their hands.

I pass now to a class of vessel—the fast protected cruisers—intended to take the place and perform the duties of the old frigates. Of these I will take as types H.M.S. *Medusa* and the Italian cruiser *Piemonte*. The *Medusa* has a length of 265 feet, a breadth of 41 feet, a displacement of 2800 tons, and her engines have 10,010 indicated horse-power. Her armament consists of six 6-inch breech-loading guns, ten 3-pounders, four machine guns, and two fixed and four turning torpedo tubes. The *Piemonte* has a length of 300 feet, a breadth of 38 feet, a displacement of 2500 tons, and her engines of 12,981 indicated horse-power developed on the measured mile a speed of 22·3 knots, or about 26 miles. Her armament, remarkable as being the first instance of an equipment composed altogether of quick-firing guns, consists of six 6-inch 100-pounders, and six 4·7-inch 45-pounders, all with large arcs of training, ten 6-pounder Hotchkiss, four Maxim-Nordenfelt machine-guns, and three torpedo guns.

These vessels have a steel protective deck, with sloping sides from stem to stern, protecting the vitals of the ship; above and below the armour-deck the vessels are subdivided into a large number of water-tight compartments, and a portion of the vessel's supply of coal is employed to give additional protection.

With respect to the *Piemonte* the engines (vertical triple expansion) were designed and constructed by Messrs. Humphreys, Tennant, and Co. They are, in order that they may be wholly below the water line, of exceedingly short stroke, (27 inches), and the behaviour of the engines, both on their trials here and in the very severe weather to which the vessel was exposed on her passage out, amply justify these eminent engineers in their somewhat bold experiment.

I might describe other cruisers, both larger and smaller than those I have selected, but I must not fatigue you, and will only in this part of my subject draw your attention to these triumphs of engineering ingenuity and skill, I mean the torpedo boats, which (whether or not locomotive, torpedoes continue to hold their own as engines of destruction), are destined, I believe, to play no insignificant part in future naval warfare.

Let me illustrate the marvels that have been achieved by the great English engineers who have brought these vessels to their present state of perfection by giving you a few particulars concerning one or two of them.

A first-class torpedo boat by Yarrow has a length of 135 feet, a breadth of 14 feet, a displacement of 88 tons, and with engines of 1400 indicated horse-power attains a speed of a little over 24 knots.

A slightly larger boat, built for the Spanish Government by Thorneycroft, has a length of 147 feet 6 inches, a breadth of 14 feet 6 inches, and with engines of 1550 indicated horse-power, has attained a speed of a little over 26 knots.

It is interesting to note that the engines of the first-named torpedo boat develop nearly exactly the same power as those of the 90-gun ship, the *Cæsar*, and the engines of the second-named but little less than that developed by the *Duke of Wellington*, two vessels which you will remember I have taken as types of the second- and first-rate men-of-war of thirty-five years ago.

The weight of the engines of the *Duke of Wellington* and the *Cæsar* would be approximately 400 tons and 275 tons, while that of the torpedo boats is about 34 tons.

But if these results are sufficiently remarkable, the economy attained in the consumption of coal is hardly less striking.

The consumption of coal in the early steam battle-ships was from 4 to 5 lbs. per indicated horse-power per hour, and occasionally nearly reached 8 pounds.

At the present time in good performances the coal consumption ranges from $1\frac{1}{2}$ to $1\frac{3}{4}$ lbs. per indicated horse-power per hour under natural draught, and from 2 to $2\frac{1}{4}$ lbs. per hour with forced draught.

In war-ships the engines are designed to obtain the highest possible power on the least possible weight, and this for a comparatively short time, and, further, have to work at such various powers, that the question of economy must be a secondary consideration.

With the different conditions existing in the mercantile marine, more economical results may be expected, and I believe I shall not be far wrong in assuming that in special cases $1\frac{1}{2}$ lbs. may possibly have been reached; but I have not been able to obtain exact information on this head.

Turning now to the guns, let me refer first to those which were in use thirty-five years ago, and which formed the armaments of the ships of those days, and of the fortresses and coast defences of the United Kingdom and colonies.

The whole of these, with the exception of a few very light guns, were made of cast-iron. I have already alluded to the small amount of machine work (not of a very refined character) expended on them. Although the heaviest gun in use was only a 68-pounder, there were no less than sixty different natures of iron ordnance. Of the 32-pounder alone there were as many as thirteen descriptions, varying in length and weight. Of these thirteen guns, again, there were four separate calibres ranging from 6·41 inches to 6·3 inches, and as the projectile was the same for all, the difference fell on the windage. This varied, assuming gun and projectile to be accurate, from about 0·125 to 0·250, so that it may easily be conceived the diversity of the tables of fire for this calibre of gun were very great. And although from the simple nature of the guns, and the absence of anything like mechanical contrivance connected with them, it was quite unnecessary to give to them the care and attention that are absolutely indispensable in guns of the present day, it must not be supposed that they were altogether free from liability to accident and other defects.

I had occasion recently to look into the question of the guns employed in the siege of Sebastopol, and found that in that great siege no less than 317 iron ordnance were used by this country. At the close of the siege it was found that 8 had burst, 101 had been condemned as unserviceable, while 59 were destroyed by the enemy's fire.

The 95 cwt. 68-pounder gun seems to have been about the largest gun that could safely be made of cast-iron, and that in it the limit of safety was nearly reached, was shown by the fact that a serious percentage of this calibre burst or otherwise failed. With the spherical shot the column of metal per unit of area to be put in motion by the charge was small, and to this the guns probably owed their safety.

When the same charge was used, and cylinders representing double, treble, or quadruple the normal weight of the shot were fired, the end was rapidly reached, the guns frequently bursting before cylinders four or five times the weight of the shot were employed.

But the fact that a stronger and more reliable material than cast-iron was necessary, was shortly to be emphasized in a much more striking manner. The great superiority of rifled to smooth-bored ordnance in every respect, in power, in range, in accuracy, in destructive effect of shrapnel and common shell, was in this country demonstrated by Lord Armstrong and others. This led to numerous attempts to utilize cast-iron for rifled ordnance. The whole of these efforts resulted in failure. Although the charges were feebler than with smooth-bored guns, these experimental guns burst one after the other with alarming rapidity, generally before many rounds had been fired. The matter was not made much better when the expedient was adopted of strengthening these guns by hoops or rings shrunk on externally. Failures with this arrangement were little less frequent, the cast-iron bursting under the jackets, and the only plans in which cast-iron was used with any success were those proposed respectively by Sir W. Palliser and Mr. Parsons, who inserted, the one a coiled wrought-iron, and the other a steel tube in a cast-iron gun block.

But the country that suffered most severely from the use of cast-iron was the United States. Their great civil war took place just when efforts were being made in every country to introduce rifled artillery. Naturally every nerve was strained to manufacture these guns, and naturally the resources that came most readily to hand were first employed.

A report presented by the Joint Committee on Ordnance to the United States Senate in 1869 gives the history of these guns, which were nearly all either cast-iron or cast-iron reinforced with hoops in the way I have described. I have heard the existence of internal strains disputed, but in this report we read that ten guns burst, that is, flew to pieces, when lying on chocks, without ever having had a shot fired from them, and 98 others cracked or became ruptured under like conditions.

In the "Summary of Burst Guns" in the same report, it is stated that 147 burst and 21 were condemned as unserviceable; 29 of them being smooth-bore and 139 rifled ordnance. But perhaps the most striking passage is that which relates that in the action before Fort Fisher *all* the Parrott guns in the fleet burst, and that by the bursting of five of these guns during the first bombardment, 45 men were killed and wounded, while only 11 men were killed or wounded by the enemy's fire.

The muzzle velocity given by the smooth-bored, cast-iron guns may be taken approximately at 1600 f.s., and at the maximum elevation with which they were generally fired their range was about 3000 yards. The 32-pounder, with a charge of one-third the weight of the shot and an elevation of 10°, gave nearly 2800 yards, and the 68-pounder, with a charge of about one-fourth, nearly 3000 yards. The same gun, with an eccentric shot, and an elevation of 24°, gave a maximum range of 6500 yards.

But it must not be supposed because the range tables gave 3000 yards as practically the extreme range of the ordnance of 35 years ago, that our guns possessed any high efficiency at that distance. At short distances, from 300 to 500 yards, dependent on the calibre, the smooth-bored guns were reasonably accurate, but the errors multiplied with the distance in so rapidly increasing a ratio, that long before a range of 3000 yards was attained the chance of hitting an object became extremely small.

It is desirable to give some idea of the accuracy, or, rather, want of accuracy, of these guns.

In 1858 I was appointed secretary to the first Committee on Rifled Cannon, and the early experiments showing how extraordinary was the accuracy of the new weapons, it became a matter of importance to devise some means of comparing in this respect the old and the new guns.

The plan I proposed was one which has since been followed by the artillerists of nearly all countries. It was to calculate the probable error in range and the probable error in deflection, and from these data the area within which it would be an even chance that any given shot would strike; or, in other words, that area within which, out of a large number of rounds, half that number would fall. This area was for the smooth-bored gun at a range of 1000 yards, 147·2 yards long by 9·1 yards broad, or 1339·5 square yards, while the similar area for the rifled gun at the same range was 23·1 yards long by 0·8 yards broad, or an area of 18·5 square yards. But the great decrease of accuracy due to an increase of range with the smooth-bore guns is especially remarkable. Experiments showed that with the smooth-bored gun an increase of range of only 350 yards more than doubled the error in deflection, and made the area selected for comparison 206 yards long, by 20·2 broad, or 4161 square yards, as nearly as possible trebling the area for an increase in range of 35 per cent.

But I have not done yet. These experiments were made with the same lots of powder carefully mixed, and the irregularities in velocity would be such as are due to manufacturers' errors only. But the variations in the energy developed by the gunpowder employed have still to be considered. In 1860, being then an associate member of the Ordnance Committee, I carried on for the Government the first electro-ballistic experiments made in this country. My attention was early called to the great variation in energy developed by powders recently made and professedly of the same make, and I pointed out that in my experiments the variations between one lot of powder and another amounted occasionally to 25 per cent. of the total energy developed. It is unnecessary to say that on service, and when

powder had been subjected to climatic influences, the variations would have been much greater.

The variations in energy of new powder were chiefly due to the method of proof then in use, the Eprouvette mortar, than which nothing can be conceived better adapted for passing into the service powders unsuitable for the guns of that time.

But with the want of accuracy of the gun itself, and the want of uniformity in the propelling agent, it may easily be conceived that a limit was soon reached beyond which it was mere waste of ammunition to fire at an object even of considerable size, and we can appreciate the reasons which led our naval commanders, whenever possible, to close with their enemy.

When we come to consider guns of the present day, the first point that attracts our attention is the enormous increase in the size and weight of the larger natures. It may fairly be asked, indeed, if, weight for weight, the modern guns are so much more powerful than the old, and, if we have command of such great ranges, why such heavy guns should be necessary.

The answer to this, of course, is that it has been considered essential to have guns capable of piercing at short distances the thickest armour which any ship can carry, and this demand has led us from guns of 5 tons weight up to guns of 110 and 120 tons weight, and to the development of the important mechanical arrangements for working them, to which I shall presently refer.

On the principles which guide the construction of these large guns I shall say little, both because the subject is too technical to be dealt with in an address, and because the practice of all nations, though differing in many points of detail, in essentials is closely accordant.

On three points of construction we lay particular stress in this country. These points are: That the gun shall be strong enough to resist the normal working pressure, even if the inner tube or barrel be completely split. That whether we regard the gun as a whole, or the parts of which it is composed, the changes of form should be as little abrupt as possible, and that any sharp angle or corner must be absolutely avoided.

As in principles of construction, so in material employed, is the practice of the great gun-making nations closely agreed. The steel employed is ductile and subjected to severe specifications and tests, which differ slightly one from the other, but exact, in effect, qualities of steel substantially the same. So far as I know, the application of the tests in this country is more severe than in any other, and I take this opportunity of entering my protest against the statement which I have seen more than once in the journals of the day—that English gun-steel is in any way inferior to any that is produced in any part of the world. Sheffield has in no respect lost its ancient reputation in the art of steel-making, and to my certain knowledge has supplied large quantities of steel, admitted to be of the first quality, to gun-makers of the Continent. The steel made by Sir J. Whitworth & Co. has likewise long been in great repute both at home and abroad, and looking at the care devoted to the subject by the Government, and the eagerness with which improvements in the quality and mode of manufacture are sought for and acted on by the steel-makers, we may be absolutely certain that to the best of our knowledge the most suitable material is used in the construction of our guns.

As many of you are aware, the mild steel which is used for the manufacture of guns is after forging and rough-boring subjected to the process of oil-hardening, being subsequently annealed, by which process it is intended that any detrimental internal strain should be removed. This process of oil-hardening, introduced first by Lord Armstrong in the case of barrels, is now almost universally adopted for all gun forgings. Of late, however, there has been considerable discussion as to whether or not this oil-hardening is necessary or desirable; and while admitting the increase of the elastic limit due to the process, it is asked whether the same results would not be obtained by taking a steel with, for example, a higher percentage of carbon, and which should give the same elastic limit, and the same ductility. The advocates of oil-hardening urge that steel with low carbon, duly oil-hardened to obtain the elastic limit and strength desired, is more reliable than steel in which the same results are reached by the addition of carbon. Those who maintain the opposite view point to the uncertainty of obtaining uniform results by oil-hardening, to the possibility of internal strains, and to the costly plant and delay in manufacture necessary in carrying it out. The question raised is undoubtedly one of great importance, but it appears to me to be one concerning which it is quite within our power in a comparatively short time, by properly arranged experiments, to arrive at a definite conclusion.

Sir F. Abel has in his Presidential Address given us so masterly a *résumé* of the present state of the steel question in its metallurgical and chemical aspects that it is unnecessary for me to add anything on this head. I will only remark that in selecting steel for gun-making, individually I should prefer that which is on the side of the low limit, to that which is near the high limit, of the breaking weight prescribed by our own and other Governments. I have this preference because, so far, experience has taught us that these lower steels are safer and more reliable than the stronger—and in guns we do not subject, and have no business to subject, the steel to stresses in any way approaching that which would produce fracture.

Of course if our metallurgists should give us a steel or other metal which with the same good qualities possesses also greater strength, such a material would by preference be employed, but it must not be supposed that the introduction of such new material would enable us, to any great extent, to reduce the weight of our guns. As a matter of fact, the energy of recoil of many of our guns is so high that it is undesirable in any case materially to reduce their weight. As an illustration, I may mention that some time ago, in re-arming an armour-clad, the firm with which I am connected was asked if by using the ribbon construction it would be possible, while retaining the same energy in the projectile, to reduce the weight of the main armament by three tons per gun. The reduction *per se* was quite feasible, but when the designs came to be worked out it was found that, on account of the higher energy of recoil, no less than 4 tons weight per gun had to be added to strengthen the mounting, the deck, and the port pivot fastenings.

The chamber pressures with which our guns are worked do not generally exceed seventeen tons per square inch, or say 2500 atoms. It must not be supposed that there is any difficulty in making guns to stand very much higher initial tensions; but little would be gained by so doing. Not only can a higher effect be obtained from a given weight of gun if the initial pressure be kept within moderate limits, but with high pressures the erosion (which increases very rapidly with the pressure) would destroy the bores in a very few rounds.

In fact, even with the pressures I have named, the very high charges now employed in our large guns (1060 lbs. have frequently been fired in a single charge), and the relatively long time during which the high temperature and pressure of explosion are maintained, have aggravated to a very serious extent the rapid wear of the bores. In these guns, if the highest charge be used, erosion, which no skill in construction can obviate, soon renders repair or relining necessary. Reduced charges, of course, allow a materially prolonged life of the bore, and there is also a very great difference in erosive effect between powders of different composition, but giving rise in a gun to the same pressures. Unfortunately, the powder which has up to the present been found most suitable for large guns is also one of the most erosive, and powder-makers have not so far succeeded in giving us a powder at once suitable for artillery purposes, and possessing the non-eroding quality so greatly to be desired.

An *amide* powder made by the Chilworth Company, with which I have, not long ago, experimented, both gave admirable ballistic results, and at the same time its erosive effect was very much less than that of any other with which I am acquainted. It is by no means certain that the powder would stand the tests which alone would justify its admission into the service, but the question of erosion is a very serious one, and has hardly, I think, received the attention its importance demands. No investigation should be neglected which affords any prospect of minimising this great evil.

On the introduction of rifled artillery the muzzle velocities, which you will remember had been with smooth-bore guns and round shot about 1600 f.s., were, with the elongated projectiles of the rifled gun, reduced to about 1200 f.s. In the battle between plates and guns these velocities were with armour-piercing projectiles gradually increased to about 1400 f.s., and at about this figure they remained until the appointment by the Government of a Committee on Explosives. By the experiments and investigations of this committee it was shown that, by improved forms of gunpowder and other devices, velocities of 1600 f.s. could be obtained without increasing the maximum pressure, and without unduly straining the existing guns. Similar advances in velocity were nearly simultaneously made abroad,

but in 1877 my firm, acting on independent researches on the action of gunpowder made by myself in conjunction with Sir F. Abel, constructed 6-inch and 8-inch guns which advanced the velocities from 1600 to 2100 f.s., and this great advance was everywhere followed by a reconstruction of rifled artillery.

With the present powder the velocities of the powerful armour-piercing guns, firing projectiles considerably increased in weight, may be taken at from 2000 to 2100 f.s. The distance of 3000 yards, which I said practically represented the extreme range of smooth-bored guns, is attained with an elevation of only 2° in the case of the 68-ton gun, and of 3½° in the 4·7-inch quick-firing gun, while at 10° the ranges are 9800 and 5900 yards respectively, and, as an instance of extreme range, I may mention that with a 9·2-inch gun a distance of over 13 miles has actually been reached.

Nor is the accuracy less remarkable. Bearing in mind the mode of comparison which I have already explained, at 3000 yards range the 68-ton gun would put half its shot within a plot of ground 7·2 yards long by 0·3 broad, and the 4·7-inch gun within a plot 19 yards long by 1·3 broad; or, to put it in another form, would put half their rounds in vertical targets respectively 0·92 yards broad by 0·34 yards high and 1·3 yards broad by 1·6 yards high.

But it cannot be assumed that we are at the end of progress. Already, with the amide powder we have obtained nearly 2500 f.s. in a 6-inch gun with moderate chamber pressures, and with the cordite originated by the Committee on Explosives, of which Sir F. Abel is president, considerably better results have been obtained. I have elsewhere pointed out that one of the causes which has made gunpowder so successful an agent for the purposes of the artillerist is that it is a mixture, not a definite chemical combination; that it is not possible to detonate it; that it is free, or nearly so, from that intense rapidity of action and waves of violent pressure which are so marked with nitro-glycerine and other kindred explosives.

We are as yet hardly able to say that cordite in very large charges is free from this tendency to detonation, but I think I may say that up to the 6-inch gun we are tolerably safe; at least, so far, I have been unable, even with charges of fulminate of mercury, to produce detonation. I need not remind you that cordite is smokeless, and that smokeless powder is almost an essential for quick-firing guns, the larger natures of which are day by day rising in importance.

I now come to the third part of my subject—the modes which are now adopted of mounting and working the ordnance I have described. I have alluded to the carriages, which, at the beginning of the century, were made of wood, and were worked solely by handspikes. Thirty-five years ago they were but little changed, although in the case of pivot guns screws for giving elevation, and blocks and tackle for training had been introduced, but timber was still the material employed. A strong prejudice long existed in both services against iron for gun carriages, as it was believed that iron carriages would be more difficult to repair, and that the effect on the crew of splinters would be much more serious.

But when the experiment of firing at both natures was made at Shoeburyness, with dummies to represent the crews, it was found both that the wooden carriage was far more easily disabled than the wrought iron, and that the splinters from the wooden carriages were far more destructive.

In all other respects, the superiority of wrought iron as regards unchangeability, durability, and strength, was so apparent, that iron, and later steel, rapidly displaced wood. No gun carriages, not even field, are now made of that material. It is impossible, within moderate limits, to give even a sketch of the various forms of mountings that have, as the science of artillery has progressed, been designed to meet the constantly changing conditions of warfare. I shall confine myself to the description of certain types of carriages, dividing these generally into three classes, viz., those for guns of the largest class, which require power to work them; those for guns of medium size, in which, by special arrangements, power is dispensed with; and those for guns of a smaller class, which are particularly arranged for extremely rapid fire.

With respect to the first class. On the adoption of heavily armed, revolving turrets of the Cowper-Coles type, in which the guns are trained for direction by revolving the turret, the first idea which naturally presented itself was to utilize steam power for this heavy work. It was, however, soon recognized that, on account of its elasticity steam did not give the necessary steadiness and control of movement essential for accuracy of aim, and water under pressure was employed as the means of transmitting the power from the steam-engine to the machinery for rotating the turret and working the guns.

On land, where an accumulator can be employed, a small steam-engine kept constantly at work is used; but at sea, where accumulators, whether made to act by the pressure of steam, air, or springs, are inadmissible, a very much larger engine is employed sufficiently powerful to supply water to perform all the operations ever carried on together. When little or no work is required, the engine automatically reduces its speed till it merely creeps, so that little or no power is consumed.

The mode of mounting the guns differs somewhat according as they are intended to be placed in a barbette or in a turret. Our guns have gradually been increased in length, and are now so long (our largest has a length of nearly 45 feet) that it is impossible to provide an armoured turret of sufficient size to protect the forward part of the gun, and under these circumstances it is a grave question whether it is worth while to devote so much armour to the protection of what is after all the strongest part of the gun.

Of the eight new battle-ships now building, seven are to have their guns mounted *en barbette*, and one is to be provided with armoured turrets. In either case the guns and their machinery are carried on revolving turntables of practically the same form. These turntables are placed in an armoured redoubt, and the guns, when horizontal, are entirely above the armour, but in the case of the ship provided with turrets the breech ends of the guns are covered in, with the turrets placed as an addition on the turntables.

The extra weight required thus to protect the breech ends of the guns is for this ship about 550 tons.

As the hydraulic machinery for these new ships differs but slightly from that fitted on ships of the *Rodney* and *Nile* classes, the same description will cover all these vessels. The armoured barbette battery at each end of the ship is made of a pear shape, in order to provide for a pair of ammunition hoists and hydraulic rammers at its narrower end.

These ammunition hoists come right up into the armoured barbette and descend to the shell-room and magazine decks, forming the channel by which the projectiles and charges are rapidly supplied to the guns; and it must be remembered that the weight to be lifted for a single round, including powder and projectile, with the necessary cases, considerably exceeds a ton. The cage in each hoist is worked by hydraulic cylinders with double wire-ropes, and in case of breakage, automatic safety gear is fitted to arrest and lock the cage.

While on the ammunition deck the cages are charged simultaneously from either side, and when hoisted to the battery-deck are automatically slowed, and then stopped at the proper position for loading the guns, much depends upon the service of ammunition by these hoists being protected from interruption, and in the event of derangement of the cage, independent tackle, worked by an hydraulic capstan, is provided to take its place, and a few rounds can also be stowed within the battery.

In intimate connection with the ammunition hoists are the hydraulic rammers on the ammunition deck for charging the cages, and in the battery for loading the guns. To reduce their length within reasonable limits they are made telescopic, and they are fitted with indicators to show when the charges are home.

In the shell-rooms hydraulic cranes and traversing bogies are fitted to convey the shell to the base of the ammunition hoist, so that a projectile is transported from the place where it is stowed to the shot-chamber of the gun without manual labour of any sort except that of moving the various levers to set the hydraulic machinery in motion. In the magazines hydraulic bollards are provided for hoisting and transporting the powder-cases by means of overhead runners. Hand-gear is provided as an alternative in both magazine and shell-rooms.

Each turntable carrying the guns and their fittings is rotated by a pair of entirely independent three-cylindered engines, each engine being of sufficient power to rotate the turntable at the speed of one revolution per minute. The gear for controlling them is worked from two or three look-out stations, at either or any of which the officer has to his hand the means of elevating, training, sighting, and firing either one or both guns. The turning-engines are fitted with a powerful spring break, which will hold in a seaway, but which is taken off automatically when the water is admitted to start the engines. Easy control is obtained by

the use of servo-motor valves, so that the handwheel is smal and requires but little power to move it. It only remains to describe as shortly as possible the system of mounting the guns on the turntable. The guns are trunnionless, to allow them to be as close together as possible, with the view of reducing to the smallest possible size the diameter of the turntables. The carriages are cradles of steel grooved to correspond with rings turned on the guns, and with straps by which the guns are secured to the cradles. The carriages are mounted without rollers or wheels on slides formed of steel beams of great strength, pivoted at their front ends and supported on hydraulic presses, by which they are bodily raised or lowered to give the guns elevation or depression. In the case of the turret this system gives the smallest possible port. The loading of the gun is effected while the gun is at extreme elevation, a position which is easily determined by dropping the slide on to fixed stops, and which gives the best protection for the breech mechanism, for the hoist and rammers. The operations of unlocking the breech-block, withdrawing it, traversing it, inserting a loading tray, and, after completing the loading, performing the same operations in reverse order, are all done by hydraulic power, and the fittings are so devised that, unless the gun is properly locked and run out, it cannot be fired.

In certain foreign vessels provided with the hydraulic breech mechanism, a valve has been arranged which makes in their proper order, and in that order only, the eight or ten movements necessary to open and close the breech of the gun, but this system has not been adopted in our own navy.

The sights are carried on the top of the turntable, or, in the case of a turret, on the turret roof, and are worked automatically by an arc attached to the gun slide, gearing into cog-wheels, with shafting reaching to each sighting position.

The system of recoil press adopted on all these ships is that which lends itself most readily to employment also as a running-in-and-out press. It consists of a simple cylinder carried in the middle of the slide, having working in it a ram with piston, attached at the front end to the carriage. Spring-loaded valves are placed in the recoil ram piston and at the end of the cylinder, and by these the water escapes when the gun recoils. The water which passes through the cylinder valves runs to the exhaust-pipe, while that which passes through the piston valve remains in the front of the cylinder, and prevents the gun charging out again. When the recoil press is used to run the gun in and out, these valves are inoperative, as they are loaded much above the working pressure in the hydraulic mains. The high pressure of recoil does not enter the hydraulic mains, as the supply to the rear of the press, where alone the high pressure of recoil exists, is made backwards and forwards, through a valve which shuts itself automatically when not in use.

Before leaving the working by power of heavy guns, there is one example of mounting a pair of guns *en barbette* which, although it has many points in common with the system I have just described, has also some points of difference, which it may be worth while to note.

Objections have sometimes been urged to the fixed loading station on the ground that it is necessary to bring the guns to it and lock them there until sponged and loaded, thereby involving, not only a loss of time, but, under certain conditions, exposing them more to the enemy's fire.

In ships of the *Re Umberto* type, what is termed an all-round loading is obtained by bringing up the ammunition through a central hoist to the deck below the turntable. From this central hoist it is transferred to two other hoists, which are carried on the turntable behind the guns. The transfer is made by hand for the powder, and by sliding down a tray for the projectile, this work being performed by men on the deck below the turntable. The hydraulic rammers are fixed to the turntable, and are very much shortened by being made with more rams. In spite of this arrangement, however, the hoists are rather cramped, and the breech mechanism has to be made to pass from behind the gun, so as to permit the gun to recoil, and the gun is rather further forward than usual when run out.

With these reservations, however, the system has advantages: the reduction in the armour required to protect the turntable and its machinery is considerable, and the redoubt being round instead of pear-shaped, presents a smaller and stronger surface to the enemy when broadside on.

I very much doubt, however, whether with this system there can be any advantage in rapidity of fire. Training to the loading station is in our navy very quickly done, and the turntable is rotated while the guns are being run in or out.

It is hardly necessary to say that hydraulic machinery for guns was worked out by my friend and late partner Mr. George Rendel, and up to the end of 1881 all details connected therewith were made under his management.

I ought perhaps to give you some idea of the rate at which these heavy guns worked by power can be fired.

In the case of the *Benbow*, with the 110-ton gun the time from "load" to "ready" was 2½ minutes. In the firing trials of the *Trafalgar* four rounds were fired from one of her 68-ton guns in 9 minutes 5 seconds. In the *Colossus*, when under command of Captain Cyprian Bridge, the average from one round to another was 1 minute 45 seconds, and on one occasion, steaming at 8 knots per hour past a target at a distance of 1500 yards, she fired four rounds in six minutes, striking the target three times.

Of the mountings which are worked solely by manual power, the whole range for naval service is covered by the carriages of the type designed by Mr. Vavasseur. No single description can be made to cover all the varieties of these mountings which have been worked out to meet the diverse conditions which have arisen in the re-arming of old ships, and the fitting out of new vessels on modern and novel designs. The very general adoption of breech-loading ordnance brought with it the necessity for a mounting which would give easier access to the breech of the gun than was obtained with the long low gun-slide employed with the muzzle-loading guns. The main features of the type, therefore, are: a high slide, very short, so as not to project beyond the breech of the gun, a short low carriage carrying on either side the recoil presses, and a shield to afford protection both to the carriage and the gun crew.

The increased importance of rapid-fire guns has led in later carriages to a strong armour plate being built into the mounting as part of its structure, and to this must be added the shield above mentioned, so that the total protective thickness of plate is very considerable.

By means of a worm wheel sliding on a keyed shaft the movement of the gun for elevation or depression can be made up to the instant of firing—a decided and very important advance on the older methods.

The arrangement of the recoil-cylinders is peculiar. They are fitted with a pair of pistons with rotating valves, so adjusted as to be open when the gun is in the firing position, and to be gradually closed during recoil by studs running along rifled grooves in the cylinders; by this ingenious contrivance the area of the ports of the valves is increased and then decreased in proportion to the variation of the velocity of recoil, so that the liquid passes from one side of the piston to the other at as nearly as possible a constant velocity and under a constant pressure. The velocity of the flow through the ports, and therefore the pressure of the liquid, varies with the energy of the recoil of the gun, so that the length of the recoil is with all charges practically the same.

Even a blank charge produces nearly full recoil, and on one occasion caused one of these mountings to be reported as unserviceable, and unfit to fire a shotted round. Constant length of recoil has the advantage over constant pressure in the recoil-presses that, in the event of an unusually heavy recoil, a higher pressure in the recoil-press would in the former case be the only result, and would do no harm, as the pressure would still be much below the test-pressure; but in the latter case there would be an increased length of recoil, and, unless considerable margin were allowed, a possible destruction of the slide.

Most frequently the Vavasseur mountings are made with central pivots, and there is then little tendency for the movements of the vessel to affect the mounting, and as the weight is borne upon a ring of live rollers the greatest ease of training is obtained.

In the larger sizes the centre pivot is increased in size, and made hollow so as to provide for the passage through the centres of a powder hoist, which, after rising high enough, curves to the rear under the gun and delivers its charge at the point where it can most conveniently be drawn out for insertion in the gun. In this case a foot plate is also provided as a rear attachment to the slide, and from this the crew work the gun. This foot plate is provided with boxes for eight or ten projectiles, which are therefore ready for use at any moment and in any position of training. These mountings are fitted in the belted cruisers of

the *Orlando* class, one being carried at the fore and one at the after end of each ship.

As a sufficient proof of the value of these mountings and of the ability which has been displayed in their design, I may mention that practically all countries have adopted these carriages for modern guns, either without any alteration or with comparatively unimportant modification.

In discussing our modern ordnance I only alluded to quick-firing guns, because in their case the gun and mounting are so closely connected, the efficiency of the system depending as much upon the one as the other, that a separate description of either would be incomplete, and they are more easily described together. The great success which attended the small Hotchkiss and Nordenfelt three- and six-pounder guns led me to consider whether the same principle could not be applied to large guns, and we designed and made at Elswick the 4·7 inch and 5·5 inch quick-firing guns which were so successfully tried by the *Excellent* at Portsmouth. Subsequently, with the co-operation of Mr. Vavasseur, various improvements were made, and for the sake of uniformity in calibre a 6-inch was substituted for the 5·5-inch gun.

One of the peculiarities of these guns is in the form of the breech-screw which, while on the principle of the interrupted screw, is made conical, so as to simplify the action of opening and closing—the principle of the ordinary rifle cartridge has been extended to the ammunition for these guns. This not only allows extremely rapid loading, but secures safety from premature explosions in rapid firing. The cartridges are fired electrically, and, not having their own ignition, there is no danger of exploding them either when stowed in the magazine or if accidentally dropped in the handling.

To follow the rapid movements of a torpedo boat it is essential that there should be the most perfect control over the gun and mounting, and the most effective mode of rapid fire is to keep the gun always on the object aimed at, allowing the gun itself to fire as the breech is closed. The captain stands at the side of the gun, shielded by a guard-plate from the recoil, his shoulders braced against a shoulder-piece which is unaffected by the recoil; his eye aligns the sights; with one hand he works the elevating or training wheel, and with the other grasps the firing-trigger, or, for rapid firing, the training-wheel may be thrown out of gear, and direction given by the shoulder-piece alone. The mounting is a centre pivot, and, being on live rollers, turns with the least effort. The gun has no trunnions, but slides in a carriage which envelopes it like a sleeve. The trunnions are on this carriage, so that the two are together pivoted like an ordinary gun in a fixed lower carriage. There is no preponderance when the gun is in the forward position, and the recoil lasts for so short a time that the disturbance of the centre of gravity is not felt on the elevating-gear or shoulder-piece. The lower side of the carriage is formed into a recoil press, the piston-rod of which is attached to a horn on the rear of the gun.

There is also a spring-box, with rod attachments to the horn, by which the gun is instantly run out as soon as the recoil is expended. Efficient shields are provided to protect the crew. The revolving weight of the gun and mounting is 5 tons; yet, with the shoulder against the shoulder-piece, it can be swung through 90° in 2 seconds, and with the gear can be trained through the same arc in 5 seconds. It is possible to fire from this gun at the rate of 10 to 12 rounds per minute, and on one occasion 10 rounds were fired in 47 seconds; but perhaps the most striking experiment with the gun was made at Shoeburyness, when five rounds were fired in 31 seconds at a $6' \times 6'$ target at 1300 yards, all of which struck the object aimed at.

A trial has also been recently made between two cruisers, the one armed with ordinary breech-loading, the other with quick-firing artillery, from which it appears that when firing at a target the latter, in a given time, was able to discharge about six times the quantity of ammunition fired by the former. I need not impress upon you the significance of these facts or the importance of quick-firing armaments, especially if firing shell, possibly charged with high explosives, against the unarmoured portions of cruisers or other vessels.

The accuracy and the shell power of rifled guns have naturally had their effect upon the mountings for the land service, experiments having conclusively shown that batteries armed with guns placed in ordinary embrasures would soon be rendered untenable. Among the expedients that have been adopted or suggested to meet the altered conditions, the system of making the gun disappear behind a parapet or into a pit, with which the name of Colonel Moncrieff has been so long and so honourably associated, is more and more coming into favour as the most effective mode of protection for the gun and its mounting, as well as for the gun detachment. During the last ten years much attention has been devoted to the designing of various mountings on this system for all weights of guns from 3 up to 68 tons.

In the earliest carriages of this type the gun was raised by the descent of a balance weight, but the most successful arrangement is that in which compressed air is employed for the purpose. The 9·2-inch and 10-inch hydro-pneumatic mountings are the largest sizes as yet adopted into the English service, and a description of them will serve for that of the type generally.

The gun on this system is raised by compressed air stored in several chambers, and acting through the medium of a fluid upon a recoil ram.

On the recoil of the gun the liquid is driven from the cylinder by the incoming ram into the lower parts of the air chambers, so that as much as is required of the energy of recoil is stored up by the compression of the air, and is used to raise the gun for the next round. The gun is raised up and lowered on two heavy beams pivoted to the lower carriage. Two long light elevating rods, pivoted at one end to the breech of the gun, at the other to the lower carriage, hold the gun in correct position as it rises or falls; the elevation is changed by moving the position of the lower ends of the elevating rods. This can be done when the gun is down without disturbing it, and consequently with very little labour. The effect of the change is apparent after the gun rises, when any slight correction can be made if desired. Generally these mountings have been made with overhead shields placed a little below the level of the top of the gun pit, and entirely closing it. There is an aperture through which the gun rises, but which can be closed when the gun is out of action.

In the case of the 10-inch gun the total weight of the revolving mass is 80 tons. Only two men are required at the hand-wheels to revolve it—in fact, it is within the power of *one* man to do the whole work. The ordinary speed of training is 90° in 1¼ minute, while the time required to raise the gun to the firing position is 20 seconds. The speed of rising might be considerably increased, but, taking the weight of the mass in motion into account, it does not appear to be desirable to accelerate it.

At Maralunga, Spezia, in March of the present year, the first 68-ton disappearing mounting, manufactured for the Italian Government, was tried with most satisfactory results. Fifteen rounds were fired in all, some of them being made to give greatly increased energy of recoil, with the view of proving the gun and mounting.

The gun was worked entirely by hand-power, and on land no difficulty is experienced in thus dealing with it, while the system possesses the advantage that it is always ready for use should it be required, but no great alteration is necessary to adapt the mounting for use with hydraulic power.

In this case the water from the recoil press is driven through spring-loaded valves instead of into air chambers. There is, therefore, no storing up of the recoil energy, and to raise the gun to the firing position, water pressure from an accumulator kept charged by a steam-pumping engine in the usual way is employed. These guns and mountings are too large to be easily covered by an overhead shield, but they are provided with shields at the front and rear to protect the gun detachments.

Another very successful mounting for land service has been made for guns when the site is such that it is permissible to place them *en barbette*. The gun is entirely above the parapet, but the detachment is protected while loading and working the gun by a broad sloping shield carried on the gun carriage and recoiling with it. The shield is inclined so that any splinters, &c., striking it, may be deflected in an upward direction.

The carriage runs back on a long slide inclined at 5°, and at the end of the recoil is caught by a spring catch, which retains it in the run in position until the loading is finished. To load, the gun is put at extreme elevation, so that the breech may be as much under protection as possible, the charge being rammed home with a hand rammer worked by rope tackle. The slide is mounted on front and rear rollers, and has an actual central pivot. The recoil is controlled by a single Vavasseur recoil cylinder placed in the centre of the slide, and giving a constant length of recoil for all charges, so that the spring catch to retain the gun at extreme recoil for loading is always reached.

To run out after loading, the spring catch is released, and the

incline of the slide is sufficient to cause the gun to run out, which it does smartly, but is checked and brought to rest quietly by means of a controlling ram placed at the end of the recoil press.

But I must conclude. I trust I have said enough to satisfy you as to the indebtedness of the naval and military services to mechanicians and to mechanical science, but you will also understand that within the limits of an address it is impossible to give a complete survey of so large a subject, and that there are important fields I have left wholly untouched.

SECTION H.

ANTHROPOLOGY.

Opening Address by John Evans, D.C.L., LL.D., D.Sc., Treas.R.S., Pres.S.A., F.L.S., F.G.S., President of the Section.

In the year 1870 I had the honour of presiding over what was then the Department of Ethnology in the Biological Section of the British Association at its meeting in Liverpool. Since that time twenty years have elapsed, during the greater portion of which period the subjects in which we are principally interested have been discussed in a Department of Anthropology forming part of the organization of the Biological Section; although since 1883 there has been a new Section of the Association, that of Anthropology, which has thus been placed upon the same level as the various other sciences represented in this great parliament of knowledge. This gradual advance in its position among other branches of science proves, at all events, that, whatever may have been our actual increase in knowledge, Anthropology has gained and not lost in public estimation, and the interest in all that relates to the history, physical characteristics, and progress of the human race is even more lively and more universal than it was twenty years ago. During those years much study has been devoted to anthropological questions by able investigators, both in England and abroad; and there is at the present time hardly any civilized country in the world in which there has not been founded, under some form or another, an Anthropological Society, the publications of which are yearly adding a greater or less quota to our knowledge. The subjects embraced in these studies are too numerous and too vast for me to attempt even in a cursory manner to point out in what special departments the principal advances have been made, or to what extent views that were held as well established twenty years ago have had either to be modified in order to place them on a surer foundation, or have had to be absolutely abandoned. Nor could I undertake to enumerate all the new lines of investigation which the ingenuity of students has laid open, or the different ways in which investigations that at first sight might appear more curious than useful have eventually been found to have a direct bearing upon the ordinary affairs of human life, and their results to be susceptible of application towards the promotion of the public welfare. I may, however, in the short space of time to which an opening address ought to be confined, call your attention to one or two subjects, both theoretical and practical, which are still under discussion by anthropologists, and on which as yet no general agreement has been arrived at by those who have most completely gone into the questions involved.

One of these questions is: What is the antiquity of the human race, or rather what is the antiquity of the earliest objects hitherto found which can with safety be assigned to the handiwork of man? This question is susceptible of being entirely separated from any speculations as to the genetic descent of mankind; and, even were it satisfactorily answered to-day, new facts might to-morrow come to light that would again throw the question entirely open. On any view of probabilities, it is in the highest degree unlikely that we shall ever discover the exact cradle of our race, or be able to point to any object as the first product of the industry and intelligence of man. We may, however, I think, hope that from time to time fresh discoveries may be made of objects of human art, under such circumstances and conditions that we may infer with certainty that at some given point in the world's history mankind existed, and in sufficient numbers for the relics that attest this existence to show a correspondence among themselves, even when discovered at remote distances from each other.

Thirty-one years ago, at the meeting of this Association at Aberdeen, when Sir Charles Lyell, in the Geological Section, called attention to the then recent discoveries of Palæolithic implements in the Valley of the Somme, his conclusions as to their antiquity were received with distrust by not a few of the geologists present. Five years afterwards, in 1864, when Sir Charles presided over the meeting of this Association at Bath, it was not without reason that he quoted the saying of the Irish orator, that "they who are born to affluence cannot easily imagine how long a time it takes to get the chill of poverty out of one's bones." Nor was he wrong in saying that "we of the living generation, when called upon to make grants of thousands of years in order to explain the events of what is called the modern period, shrink naturally at first from making what seems so lavish an expenditure of past time. Throughout our early education we have been accustomed to such strict economy in all that relates to the chronology of the earth and its inhabitants in remote ages, so fettered have we been by old traditional beliefs, that even when our reason is convinced, and we are persuaded that we ought to make more liberal grants of time to the geologist, we feel how hard it is to get the chill of poverty out of our bones."

And yet of late years how little have we heard of any scruples in accepting as a recognized geological fact that, both on the Continent of Europe and in these islands, which were then more closely connected with that continent, man existed during what is known as the Quaternary period, and was a contemporary of the mammoth and hairy rhinoceros, and of other animals, several of which are either entirely or locally extinct. It is true that there are still some differences of opinion as to the exact relation in time of the beds of river gravel containing the relics of man and the Quaternary fauna to the period of great cold which is known as the Glacial period. Some authors have regarded the gravels as pre-Glacial, some as Glacial, and some as post-Glacial; but, after all, this is more a question of terms than of principle. All are agreed, for instance, that in the eastern counties of England implements are found in beds posterior to the invasion of cold conditions in that particular region, though there may be doubts as to how much later these conditions may have prevailed in other parts of this country. All, too, are agreed that since the deposit of the gravels considerable changes have taken place in the configuration of the surface of the country, and that the time necessary for such changes must have been very great, though those in whose bones the chill of poverty still clings are inclined to call in influences by which the time required for the erosion of the river valleys in which the gravels occur may be theoretically diminished.

On the other hand, there have been not a few who, feeling that the evidence of the existence of the human race has now been satisfactorily established for Quaternary times, and that there is no proof that what has been found in the ordinary gravels belongs to anything like the first phases of the family of man, have sought to establish his existence in far earlier Tertiary times. In the view that earlier relics of man than those found in the river gravels may eventually be discovered, most of those who have devoted special attention to the subject will, I think, concur. But such an extension of time can only be granted on conclusive evidence of its necessity; and, before accepting the existence of Tertiary man, the grounds on which his family-tree is based require to be most carefully examined.

Let me say a few words as to the principal instances on which the believer in Tertiary man relies. These may be classified under three heads[1]: (1) the presumed discovery of parts of the human skeleton; (2) that of animal bones said to have been cut and worked by the hand of man; and (3) that of flints thought to be artificially fashioned.

On most of these I have already commented elsewhere.[2] Under the first head I may mention the skull discovered by Prof. Cocchi at Olmo, near Arezzo, with which, however, distinctly Neolithic implements were associated; the skeletons found at Castelnedolo, of which I need only say that M. Sergi, who described the discovery, regarded them as the remains of a family party who had suffered shipwreck in Pliocene times; and the fossil man of Denise, in the Auvergne, mentioned by Sir Charles Lyell, who may have been buried in more recent times under lava of Pliocene date. On these discoveries no superstructure can be built. The Calaveras skull seems to have better claims

[1] See A. Arcelin, "L'Homme Tertiaire," Paris, 20 rue de la Chaise, 1889.

[2] Trans. Herts. Nat. Hist. Soc., vol. i. p. 145; "Address to the Anthrop. Inst., 1883," *Anth. Journ.*, vol. xii. p. 565.

to a high antiquity. It is said to have been found at a depth of 153 feet in the auriferous gravels of California, containing remains of mastodon, and covered by five or six beds of lava or volcanic ashes. But here again doubts enter into the case, as well-fashioned mortars, stone hatchets, and even pottery, are said to occur in the same deposits. In the same way the discoveries of M. Ameghino at the mouth of the Plata, in the Argentine Republic, require much further corroboration.

The presumably worked bones which I have placed in the second category, such as those with incisions in them from St. Prest, near Chartres, the cut bones of Cetacea in Tuscany, the fractured bones in our own crag-deposits, and numerous other specimens of a similar character, have, by most geologists, been regarded as bearing marks entirely due to natural agencies. It seems more probable that in bones deposited at the bottom of Pliocene seas, cuts and marks should have been produced by the teeth of carnivorous fish, than by men who could only have lived on the shores of the seas, and who have left behind them no instruments by which such cuts as those on the bones could have been produced.

As to the third category, the instruments of flint reported to have been found in Tertiary deposits, those best known are from St. Prest and Thenay, in the north-west of France, and Otta, in Portugal.

These three localities I have visited; and though at the two former the beds in which the flints were said to have been found are certainly Pliocene, there is considerable doubt in some cases whether the flints have been fashioned at all, and in others, where they appear to have been wrought, whether they belong to the beds in which they are reported to have been found, and have not come from the surface of the ground. Even the suggestion that the flints of Thenay were fashioned by the Dryopithecus, one of the precursors of man, has now been retracted. At Otta the flakes that have been found present, as a rule, only a single bulb of percussion, and, having been found on the surface, their evidence is of small value. The exact geological age of the beds in which they have occurred is, moreover, somewhat doubtful. On the whole, therefore, it appears to me that the present verdict as to Tertiary man must be in the form of "Not proven."

When we consider the vast amount of time comprised in the Tertiary period, with its three great principal subdivisions of the Eocene, Miocene, and Pliocene, and when we bear in mind that of the vertebrate land animals of the Eocene no one has survived to the present time, while of the Pliocene but one—the hippopotamus—remains unmodified, the chances that man, as at present constituted, should also be a survivor from that period seem remote, and against the species *Homo sapiens* having existed in Miocene times almost incalculable. The *à priori* improbability of finding man unchanged, while all the other vertebrate animals around him have, from natural causes, undergone more or less extensive modification, will induce all careful investigators to look closely at any evidence that would carry him back beyond Quaternary times; and though it would be unsafe to deny the possibility of such an early origin for the human race, it would be unwise to regard it as established except on the clearest evidence.

Another question of more general interest than that of the existence of Tertiary man is that of the origin and home of the Aryan family. The views upon this subject have undergone important modification during the last twenty years. The opinions based upon comparative philology alone have received a rude shock, and the highlands of Central Asia are no longer accepted without question as the cradle of the Aryan family, but it is suggested that their home is to be sought somewhere in Northern Europe. While the Germans contend that the primitive Aryans were the blue-eyed dolichocephalic race, of which the Scandinavians and North Germans are typical examples, the French are in favour of the view that the dark-haired brachycephalic race of Gauls, now well represented in the Auvergne, is that of the primitive Aryans. I am not going to enter deeply into this question, on which Canon Isaac Taylor has recently published a comprehensive treatise, and Mr. Frank Jevons a translation of Dr. Schrader's much more extensive work, "The Prehistoric Antiquities of the Aryan Peoples." Looking at the changes that all languages undergo, even when they have the advantage of having been reduced into the written form, and bearing in mind the rapidity with which these changes are effected; bearing in mind, also, our extreme ignorance of the actual forms of language in use among prehistoric races unacquainted with the art of writing, I, for one, cannot wonder a something like a revolt having arisen against the dogmatic assertions of those who have, in their efforts to reconstruct early history, confined themselves simply to the comparative study of languages and grammar. But, notwithstanding any feeling of this kind, I think that all must admire the enormous industry and the varied critical faculties of those who have pursued these studies, and must acknowledge that the results to which they have attained cannot lightly be set aside, and that, so far as language alone is concerned, the different families, their provinces, and mutual relations have, in the main, become fairly established. The study of "linguistic palæontology," as it has been termed, will help, no doubt, in determining still more accurately the affinities of the different forms of language, and in fixing the dates at which one separated from another, as well as the position that each should occupy on the family-tree—if such a tree exists. But even here there is danger of relying too much on negative evidence; and the absence in the presumed original Aryan language of special words for certain objects in general use ought not to be regarded as affording absolute proof that such objects were unknown at the time when the languages containing such words separated from the parent stock. Not only Prof. Huxley, but Broca and others have insisted that language as a test of race is as often as not, or even more often than not, entirely misleading. The manner in which one form of language flourishes at the expense of another; the various ways in which a language spreads even otherwise than by conquest; the fact that different races, with totally different physical characteristics, are frequently found speaking the same language, or but slightly different dialects of it—all conduce to show how imperfect a guide comparative philology may be so far as anthropological results are concerned. Of late, prehistoric archæology has been invoked to the aid of linguistic researches; but here again there is great danger of those who are most conversant with the one branch of knowledge being but imperfectly acquainted with the other. The different conditions prevailing in different countries, the degrees of intercourse with other more civilized nations, and local circumstances which influence the methods of life, all add difficulties to the laying down of any comprehensive scheme of archæological arrangement which shall embrace the relics, whether sepulchral or domestic, of even so limited an area as that of Europe. We are all naturally inclined to assume that the record of the past is comparatively complete. But in archæology no more than geology does this appear to be the case. The interval between the period of the river-gravels and that of the caves, such as Kent's Cavern, in England, and those of the Reindeer period of the south of France, may have been but small; but our knowledge of the transition is next to none. The gap between the Palæolithic period and the Neolithic has, to my mind, still to be bridged over, and those who regard the occupation of the Belgian caves as continuous from the days of the reindeer down to late Neolithic times seem to me possessed of great powers of faith. Even the relations in time between the *kjökkenmöddings* of Denmark and the remains of the Neolithic age of that country are not as yet absolutely clear; and who can fix the exact limits of that age? Nor has the origin and course of extension of the more recent Bronze civilization been as yet satisfactorily determined; and until more is known, both as to the geographical and chronological development of this stage of culture, we can hardly hope to establish any detailed succession in the history of the Neolithic civilization that went before it. In the meantime, it will be for the benefit of our science that speculations as to the origin and home of the Aryan family should be rife; but it will still more effectually conduce to our eventual knowledge of this most interesting question if it be consistently borne in mind that they are but speculations.

Turning from theoretical to practical subjects, I may call attention to the vastly improved means of comparison and study that the ethnologists of to-day possess as compared with those of twenty years ago. Not only have the books and periodicals that treat of ethnology multiplied in all European languages, but the number of museums that have been formed with the express purpose of illustrating the manners and customs of the lower races of mankind has also largely increased. On the Continent, the Museums of Berlin, Paris, Copenhagen, and other capitals have either been founded or greatly improved; while in England our ethnological collections infinitely surpass, both in the number of objects they contain and in the method

of their arrangement, what was accessible in 1870. The Blackmore Museum at Salisbury was at that time already founded, but has since been considerably augmented. In London, also, the Christy collection was already in existence, and calculated to form an admirable nucleus around which other objects and collections might cluster; and, thanks in a great degree to the trustees of the Christy collection, and in a far greater degree to the assiduous attention and unbounded liberality of the keeper of the department, Mr. Franks, the ethnological galleries at the British Museum will bear comparison with any of those in the other European capitals. The collections of prehistoric antiquities, enlarged by the addition of the fine series of urns and other relics from British barrows explored by Canon Greenwell, which he has generously presented to the nation, and by other accessions, especially from the French caverns of the Reindeer period, is now of the highest importance. Moreover, for purposes of comparison the collections of antiquities of the Stone and Bronze periods found in foreign countries is of enormous value. In the ethnological department the collections have been materially increased by the numerous travellers and missionaries which this country is continually sending forth to assist in the exploration of the habitable world; and the student of the development of human civilization has now the actual weapons, implements, utensils, dress, and other appliances of most of the known savage peoples ready at hand for examination, and need no longer trust to the often imperfect representations given in books of travel. But besides the collection at Bloomsbury there is another most important Museum at Oxford, which that University owes to the liberality of General Pitt-Rivers. It is arranged in a somewhat different manner from that in London, the main purpose being the exhibition of the various modifications which ornaments, weapons, and instruments in common use have undergone during the process of development. The skilful application of the doctrine of evolution to the forms and characters of these products of human art gives to this collection a peculiar charm, and brings out the value of applying scientific methods to the study of all that is connected with human culture, even though at first sight the objects brought under consideration may appear to be of the most trivial character.

So far as the museums more intimately connected with anthropology are concerned, the advance that has been made has been equally well marked. The osteological collections both at the Royal College of Surgeons and at the Natural History Museum have received important accessions, especially in the craniological department; and the notable addition of the Barnard Davis collection to that previously existing in Lincoln's Inn Fields has placed the Museum of the College in the foremost rank. The Museums at Oxford and Cambridge have also received most important accessions: the one, of the Greenwell collection from British barrows; the other, of the Thurnam collection of skulls.

The value of the small hand-book for travellers, issued under the title of "Anthropological Notes and Queries," has been proved by the necessity for a new edition, towards which the British Association has made a grant. Some delay in the publication of the new issue has taken place, but I hope that the report of the Committee in charge of the work may give assurance of the book being now in a forward state.

The feasibility of assigning trustworthy marks for physical qualifications in candidates for posts either in the military or civil departments of the State has now for some time been attracting more or less of public attention, and the subject has been taken up by the Council of this Association. The result of their communications on this subject with the Government has been made known in their Report, and I need not enter into the history of the correspondence that has passed upon the question. Whatever course may at the present time be adopted, we may, I think, feel confident that eventually due weight will have to be attached to physical capacity in selection for appointments in the military branch of the public service, for which, indeed, at the present time a medical examination has to be passed. Thanks to the ingenuity of Mr. Francis Galton and others, we have now instruments at our command, not only for testing muscular force, breathing capacity, and other bodily characteristics, but also for ascertaining the closeness and rapidity of connection between the organs of seeing and hearing, and the action of the muscles required to be brought into play. In these experiments nervousness, no doubt, is to some extent a factor, but perhaps the rough-and-ready test of the South American commander was, for ascertaining the presence or absence of nervousness, even more effective. When promotion of some officer was about to be made upon the field, the general caused all the possible candidates to be arranged around him, each armed with a flint and steel and a cigarette, and he who first was satisfactorily smoking was promoted then and there.

Connected with the question of general physical capacity is that of the proper appreciation of colours, the absence of which is a fruitful source of danger, both by land and at sea. It is, indeed, impossible to say how often an apparently inexplicable accident may not have arisen from some form of colour-blindness, such as the inability to distinguish red from green, in a person in charge of a ship, a train, or of points on a railway. True, there are some forms of examination to be gone through, both by mariners and railway officials, with the view of testing their powers and correctness of vision; but it is very doubtful whether the tests employed or the manner in which the examinations are conducted can be regarded as in all respects satisfactory. For the purpose of investigating the phenomena, and, if possible, the physical causes of colour-blindness and allied defects of vision, and also with the view of suggesting improvements in the methods of determining the existence of such defects in candidates for maritime or railway employment, the Council of the Royal Society has appointed a Special Committee. Its labours, however, are not yet finished, and no report has hitherto been received from the Committee. I mention the subject as one in which all anthropologists will be interested, and the importance of which must be universally acknowledged. The most singular feature in the case is that the subject, though carefully investigated by several private inquirers, should have waited so long before being submitted to some public or quasi-public body for investigation.

The subjects of an anthropological survey of the tribes and castes in our Indian possessions, and of the continued investigation of the habits, customs, and physical characteristics of the North-Western tribes of the Dominion of Canada, were both recommended for consideration to the Council of this Association by the General Committee at the meeting at Newcastle. We have heard from the Report of the Council what has been done in the matter. The rapidity with which the various native tribes in different parts of the world are either modified, or in some cases exterminated, affords a strong argument for their characteristics, both physical and mental, being investigated without delay.

There are, indeed, now but few parts of the world the inhabitants of which have not, through the enterprise of travellers, been brought more or less completely within our knowledge. Even the centre of the dark African continent promises to become as well known as the interior of South America, and to the distinguished traveller who has lately returned among us anthropologists as well as geographers owe their warmest thanks. It is not a little remarkable to find so large a tract of country still inhabited by the same diminutive race of human beings that occupied it at the dawn of European history, and whose existence was dimly recognized by Homer and Herodotus. The story related by the latter about the young men of the Nasamones who made an expedition into the interior of Libya and were there taken captive by a race of dwarfs receives curious corroboration from modern travellers. Herodotus may, indeed, slightly err when he reports that the colour of these pygmies was black, and when he regards the river on which their principal town was situated as the Nile. Stanley, however, who states that there are two varieties of these pygmies, utterly dissimilar in complexion, conformation of the head, and facial characteristics, was not the first to rediscover this ancient race. At the end of the sixteenth century, Andrew Battel, our countryman, who, having been taken captive by the Portuguese, spent many years in the Congo district, gave an account of the Matimbas, a pygmy nation of the height of boys of twelve years old; and in later times Dr. Wolff and others have recorded the existence of the same or similar races in Central Africa. Nor must we forget that for a detailed account of an Acca skeleton we are indebted to the outgoing President of this Association, Prof. Flower. It is not, however, my business here to enter into any detailed account of African exploration or anthropology. I have made this incidental mention of these subjects rather from a feeling that in Africa, as well as in Asia and America, native races are in danger of losing their primitive characteristics, if not of partial or total extermination, and that there also the anthropologist and naturalist must take the earliest possible opportunities for their

researches. Already the day is past when the similitude drawn by Anaxilas between music and Africa holds good, and even Cornelius Agrippa could no longer maintain that he "sayeth not amisse: By God, sayeth he, Musicke is even like Affricke; it yearely bringeth foorth some straunge Beaste."[1]

I have, however, said enough on what I feel are somewhat vague and general topics, and will now ask you to devote your attention to the business of the Section, when, no doubt, many subjects of interest will be more particularly discussed.

NOTES.

WITHIN the next few days the National Association for the Promotion of Technical and Secondary Education will issue a brief "Guide to Evening Classes in London," which is the first attempt to give a systematic account of the educational work carried on in such classes throughout the metropolis. The Guide will be classified according to subjects and districts, so that an intending student can see at a glance the place, day, and hour at which classes are available in any particular subject in the district in which he lives, as well as the fee, name of instructor, and other details. The price will be 6*d.*, and the publishers will be Messrs. Cassell and Co.

THE following is a list, in brief, of subjects on which the Dutch Society of Sciences at Haarlem invite research:—A history of the mathematical and physical sciences in Holland; isomorphism; minerals in the river and dune sands on the Dutch coast; the accessory sexual glands in mammalia; heat liberated in solution of various salts in water; decomposition of water or other liquids by disruptive electric discharges within or on the surface; influence of compression in different directions on specific inductive power; determination of the form and position of the reticular micrometers used by Lacaille at the Cape of Good Hope; influence of volume of molecules on pressure of a gas; relation between density and chemical composition of transparent bodies, and the index of refraction; modification of reflected light by magnetization of some other metal than iron; methods of obtaining and fixing new varieties in cultivated plants; *rôle* of bacteria in filtration of portable waters through a layer of sand; bacteria and azotized combinations in the soil; healing after grafting.

THE Report of the Director of the Hong Kong Observatory for 1889 states that a self-recording anemometer, rain-gauge, and sunshine-recorder, have been erected by the Imperial Maritime Customs at the important station of South Cape, Formosa, and the observations are received monthly at the Observatory. Among the investigations in progress are: the collection of information respecting typhoons, from the logs of men-of-war stationed in those seas, and an investigation of the climate of Hong Kong from five years' observations; this latter work is nearly ready for press. The Report contains an interesting comparison of spectroscopic rain-band observations with the rainfall during the subsequent 24 hours; Dr. Doberck considers that the indications frequently foretold great thunderstorms which could not otherwise have been forecast from local observations. On May 29 and 30, 1889, the colony was visited by thunderstorms of unusual duration; above 22·5 inches of rain fell in 24 hours, causing floods and serious damage to property.

THE Journal of the Franklin Institute for September contains several interesting papers. Few can speak with more authority on "Precious Stones" than Mr. George F. Kunz, and his lecture delivered in February last, before the Franklin Institute, is replete with information respecting them. Under the heading "Electricity in Warfare," Lieutenant Bradley A. Fiske, U.S.N., comments upon the present condition of the art, indicates in what ways electricity is now actually employed, and what is the direction of progress. Mr. Joseph M. Wilson, the President of the Institute, continues his paper on schools, with particular reference to trades schools, and gives an account of the method of work set forth in the Science and Art Directory and in the Prospectus of the Normal School of Science. Among the other papers are the following: On fresh-water wells of the Atlantic beach, by Mr. Persifor Frazer. On the strength of gear teeth, by Mr. Samuel Webber; and on the electrolytic method as applied to palladium, by Messrs. E. F. Smith and H. F. Keller.

THE *Monthly Weather Review* issued by the Meteorological Service of the Dominion of Canada consists of telegraphic reports of observations received for the purpose of weather predictions and of reports of storms received by mail. Tables of temperature, pressure, wind, and precipitation are given, together with the records of sunshine and auroræ. The total number of storm warnings issued last month was 93, of which 77 or 82·8 per cent. were verified. Of the 77 warnings in connection with the direction of the wind, 66 or 85·7 per cent. were fully verified, and 72 or 93·5 partly verified. The steps made in the prediction of weather form an important factor nowadays in commercial life, and in Canada forecasts are posted up nightly at every telegraph station.

WE have received from America the summary of the weather during the last month, and also the forecast for September. The review shows that on the whole fine weather has prevailed, although occasionally disturbed by a few storms. The first storm of note was central on the 14th, about lat. 55° N., longitude 25° W., and was accompanied by moderate to strong gales, and high seas; the second moved from Southern New England to Nova Scotia on the 27th. The forecast indicates fine weather, with occasional gales north of the 35th parallel. Less fog will be found along the transatlantic steamship routes, and little ice will be encountered off the Grand Banks. An accompanying chart gives a brief but complete statement as regards these dangerous storms. A new series of storm signals at Havana were commenced in August, 1889, and this year night-signals have been added, details of these being given in an accompanying table. There is also a list of charts that have been published and corrected during the month of August, and information respecting dangerous obstructions to navigation along the coast.

WE have received from Mr. Edward Stanford, a *résumé* of the publications of the Ordnance Survey for England and Wales, with an introductory description of the survey by Major Francis P. Washington, R.E. The new 1-inch general map is reduced from the 6-inch maps, and will consist of 360 small sheets, 178 of which have been already published. This survey is well adapted for walking or driving purposes, and residential maps can be made up for 10, 15, or 20 miles round any centre. In this catalogue the particulars of each county are given in alphabetical order, and the mounting details will be found very useful to those who use maps to a great extent. At the end of the pamphlet there are some illustrations of various neat and handsome methods of mounting these maps for both library and schoolroom purposes.

A PAMPHLET on "Acoustics in Relation to Wind Instruments," by D. J. Blackley, consists of a series of lectures given by him to the students at the Royal Military School of Music, Kneller Hall, in May 1887. They have been revised and somewhat amplified, and now form a general sketch of the subject under consideration, and will be useful to those desirous of understanding the principles underlying the construction and use of wind-instruments, the illustrations of wave-motion given in them not being confined only to experiments with cylindrical tubes. There is an appendix on musical pitch, which has been

[1] "Vanitie of Sciences," cap. 17.

written with special reference to military and orchestral wind bands.

IN the number of *La Nature* for September 6 there is a detailed account of an ingenious application of the properties of iodide of nitrogen to photometry. The photometer, invented by M. Lion, is based on the fact that equal surfaces of iodide of nitrogen, preserved under its mother-liquor, and exposed for equal times to lights of equal intensities, evolve equal quantities of nitrogen. Two vessels are connected by a differential manometer, and when the rate of evolution of the nitrogen is the same in each, the manometer is unaffected. It is stated that the iodide of nitrogen, kept in the mother-liquors in which it has been prepared, is perfectly safe to handle. In practice, owing to the difficulty of exactly balancing the two halves of the apparatus, a method analogous to "weighing by substitution" is employed. The accuracy attainable in the measurements is not stated. In the same number another photometer of considerable theoretical interest is described. It is the invention of MM. Seguy and Verschaffel, and was described by them on September 1 at the Academy of Sciences, Paris. It is based upon the principle of Crookes' radiometer, but the disks, instead of being free to rotate, are suspended by a silk fibre, and with an indicating needle and divided circle, form a torsion balance. An alum cell is placed in front of the instrument, which, as a photometer, appears to be very sensitive, indicating 1-100th of a standard candle. Moreover, two instruments can be constructed, which with light of the same intensity give the same readings, an important practical advantage. So long as these instruments are used to compare lights of the same quality, there seems to be no doubt that they can both be made to yield results of practical value, and comparable with each other. It appears doubtful, however, whether the same figure would be obtained with the chemical and with the mechanical photometer, if used to compare the illuminating powers of two sources of light that differed much in character, such as an arc lamp, and a candle flame.

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus* ♀) from West Africa, presented by Mrs. Roupell; a Sykes's Monkey (*Cercopithecus albigularis* ♀) from East Africa, presented by Mr. M. Tanner; two Bonnet Monkeys (*Macacus sinicus* ♂ ♀), a Toque Monkey (*Macacus pileatus* ♀), two Ring-necked Parrakeets (*Palæornis torquatus*) from India, presented by Mrs. Julie Rule; a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Mr. W. Dodson; a Grey Ichneumon (*Herpestes griseus* ♂) from India, presented by Master Stanley Kerfoot; a Brush-tailed Porcupine (*Atherura africana*) from West Africa, presented by the Liberian Government Concessions and Exploration Co., Lt.; a Common Viper (*Vipera berus*) from Hampshire, presented by Mr. W. H. B. Pain; a Pig-tailed Monkey (*Macacus nemestrinus* ♂) from Java, deposited; two Vinaceous Turtle Doves (*Turtur vinaceus*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

Remarks.

(1 and 2) No record has yet been made of the spectrum of either of these objects. The first is described in the General Catalogue as a nebulous star, or a very small cluster; the second as "pretty bright; pretty small; round; brighter in the middle to a nucleus; mottled as if with stars; star south preceding." No very bright nebulæ are near the meridian at 10 o'clock during the present week.

(3) The spectrum of this star is a very interesting one of Group II. Instead of the spectrum being totally discontinuous, as in α Herculis and others, the bands 2, 3, 7 are well marked, whilst 4, 5, and 8 are so feeble as to be hardly visible. This species of spectrum has been explained by supposing that the meteor-swarm is still sparse and the carbon radiation consequently bright. When the positions of the feeble bands are considered, it will be seen that the explanation is complete. Band 8 extends from about λ 503·5 to λ 496, and this will therefore be partly masked by the extremity of the brightest carbon fluting starting near λ 517. Bands 4 and 5 both come within the range of the second carbon fluting, starting near λ 564, and they also will be partly obliterated when the carbon flutings are wide. None of the other bands, however, will suffer from masking in this way, and they therefore should remain dark. It will be interesting if this explanation can be tested by a direct observation of an unusual width or brightness of the carbon flutings.

(4) This star has a spectrum of Group III., and may be observed as a study of criteria.

(5) A star of Group IV. (Vogel).

(6) This is a typical star of Group VI., showing in addition to the ordinary carbon bands no less than six of the secondary bands, namely 2, 3, 4, 5, 7, and 8. Dunér remarks that the two latter are undoubtedly bands, and not lines; their wavelengths are 551 and 528 respectively, the latter almost agreeing with E of the solar spectrum. The general spectrum consists of four zones—that is, there is a certain amount of light beyond the carbon band commencing at 474. An observation of the precise character of this band would be interesting; in comets it sometimes ends abruptly at 474, sometimes fades away gradually on both sides at 468, and sometimes has two maxima, one at 468 and one at 474.

(7) Like S Vulpeculæ, referred to last week, this is a variable of comparatively short range and short period, but whereas the spectrum of the former is known to be one of Group II., that of the latter has yet to be determined. Although the period is but 168 days, we have not as yet any record of the light-curve of the star, which promises to be an interesting one from the fact that the maximum is stated as 4·7–5·7 and the minimum as 6·0–8·5 (Gore). If the spectrum be one of Group II. the shortness of the period suggests that the bands should be rather narrow, and this may be made a test observation. There will be a maximum about September 23.

A. FOWLER.

THE URANIA GESELLSCHAFT.—An interesting account of the Urania Institution at Berlin appears in the publications of the Astronomical Society of the Pacific, vol. ii., No. 9. The account was originally written for Prof. Holden by Dr. M. Wilhelm Meyer, the director of the institution. It appears that Prof. Foerster, the director of the Berlin Observatory, first proposed the formation of an observatory that should be open to the public, and his proposition was afterwards modified so as to include other branches of natural science. The project was warmly supported by Herr von Gossler, the Prussian Minister of Public Instruction, a grant of land was made, and in March 1888 a sort of joint stock company was formed having for its object simply the diffusion of knowledge. The idea having thus taken tangible form, the work of construction was begun. On July 2, 1889, the institution was opened to the public, and at the end of the year had been visited by 60,000 persons.

The astronomical department has been the main attraction from the beginning. It contains a twelve-inch refractor equatorially mounted, and electrically controlled and illuminated. The instrument is provided with a filar micrometer, a polarizing telescope, and a complete set of eye pieces ranging in power from 70 to 1300 diameters. Unfortunately neither spectroscopic nor photographic accessories have yet been supplied. Five other telescopes are possessed by the Urania Observatory, viz. a six-inch refractor, a four-inch refractor, a six-inch reflector, a two and a half inch transit instrument, and a comet seeker of five inches aperture.

The lecture theatre which forms a part of this magnificent institution, is fitted with every convenience and provided with a lantern having a light of 6000 candle-power for the projection of views on a screen. The lectures that are delivered are not all, however, devoted to astronomy, but cover the other subjects within the scope of the institution.

The Physical Department is even better supplied with apparatus than the Astronomical, and it is so arranged that visitors, by pressing different buttons, may view the spectra of various substances, the phenomena of polarization, and many electrical effects. The recent presentation of two complete phonographs by Mr. Edison gives the science collection of this Department a still higher value. A Microscopical Department is also included, and affords instruction to many.

An exceedingly well-illustrated journal, *Himmel und Erde*, has been published monthly since the foundation of the institution, and is issued free to all the members. From the recently-published Report, it appears that the cost of production of this journal considerably exceeds the receipts from subscribers, but we are glad to know that the Urania Institution is too firmly established to need its discontinuance. The number of visitors during the 268 days on which the doors of the institution have been opened is 95,000. Three hundred and thirteen lectures of about ninety minutes long have been delivered, and five hundred and eighty-two of thirty minutes duration.

Prof. Holden points out that the Lick Observatory, like the Urania Institution, is devoted to the advance of scientific knowledge, and we hope with him that the success of the latter may lead to the establishment of similar institutions in Europe and America. The opening of observatories would be much appreciated by the general public, for doubtless the Urania Gesellschaft owes much of its popularity to this step in the right direction that its directors have taken.

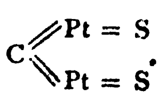
WASHBURN OBSERVATORY.—Mr. G. C. Comstock has issued the sixth volume of the "Publications of the Washburn Observatory," of which establishment he has been director since 1887. The first part contains observations with the meridian circle by Miss A. M. Lamb and Mr. Milton Updegraff. The second part is devoted to observations of double stars, by Mr. Comstock, and includes the measurement of double stars discovered at this observatory, and described in vols. i. and ii. of its Publications. The instrument employed for all of the measures was the $15\frac{1}{2}$-inch Clark equatorial telescope. As soon as the necessary apparatus is ready, a determination of the constant of aberration will be made by Loewy's method.

NEW ASTEROIDS (297) AND (298).—Two new minor planets were discovered on the 9th inst. by M. Charlois of Nice Observatory. One of them may prove to be Aschera (214).

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 8.—M. Duchartre in the chair.—On a sulphocarbide of platinum, by M. P. Schutzenberger. By passing a current of dry nitrogen charged with the vapour of carbon bisulphide over spongy platinum contained in a glass tube heated to about 400° C., the carbon bisulphide was entirely absorbed, and the platinum converted into a finely divided black powder. An examination of the product showed that it had the composition Pt_2S_2C, which may be graphically represented thus:—



The powder is very dense, and appears entirely homogeneous when microscopically examined. Neither hydrochloric nor nitric acid have any action upon it, and even with *aqua regia* there is very little action. When heated to redness in dry oxygen the powder burns, with the formation of carbon dioxide, and sulphur monoxide and dioxide, leaving a residue of pure platinum.—New researches on the gadoline of M. de Marignac, by M. Lecoq de Boisbaudran. The results of a spectroscopic examination of gadoline are given. The substance is shown to have a characteristic spectrum, thus confirming the view held by M. de Marignac, viz. that it is a new element.—On a property of certain systems of forces, by M. L. Lecornu.—On the soluble ferment of urea, by M. P. Miguel. From various considerations the author has been led to believe that in ammoniacal fermentation, the microphytes always act on the urea by means of the soluble ferment discovered by M. Musculus (Annales de Micrographie, vols. 1 and 2), and that it is not necessary to adopt the hypothesis of the destruction of urea by an act of nutrition, in order to explain the alkaline fermentation of urine.—Post-embryonic development of the kidney of the *Ammocete* by M. L. Vialleton.—On modifications of ophitic rocks of Modon (Province de Séville) by M. Salvador Calderon.—On a carboniferous bed discovered at Quenon in Saint-Aubin-d'Aubigne by M. Bezier.—Revival of the activity of Vesuvius, by M. Wiet, Consul at Naples. This is an extract of a letter to the Foreign Minister, giving an account of the actual state of Vesuvius. Lava has been issuing from an opening formed last year, and is slowly descending the central cone. Prof. Maiorano has observed that the volcanic activity of the fumaroles has ceased, and that only a small column of smoke ascends from them. It is also noted that the smoke issuing from the various openings has a different appearance from the steam and vapour generally visible.—Additional note on the extension to Switzerland of the storm of August 19, by M. Bourgeat.

BRUSSELS.

Academy of Sciences, July 5.—M. Stas in the chair.—The following communications were made:—On the ten-monthly astronomical period, by M. F. Folie.—On the characteristic property of the common surface of two liquids, by M. G. van der Mensbrugghe. The author has previously studied the properties of the common surface of two liquids which do not mix, and now gives the results of a similar study of liquids having an affinity for each other, *e.g.* water and ether or alcohol.—On new observations of the canals of Mars, and on their duplication, by M. F. Terby.—Some observations made by Mr. Stanley Williams during April and May 1890 are shown to support Schiaparelli's conclusions with respect to the nature of the surface of Mars. A plate is given containing eight views of Mars made this year by the two above-named observers.—A coronula from the gulf of St. Lawrence, by M. P. J. Van Beneden.—The Actinozoa specimens obtained by Prof. Hensen in his Plankton expedition, by Edouard Van Beneden. A larva related to that found by Semper in 1867, by the same author.—On the constitution of benzopinacoline β, by M. Maurice Delacre.—On primary co-variants, by M. Jacques Deruyts.—On the biographical notice of G. A. Hirn, recently inserted in the *Bulletin de l'Académie*, by Prof. Dwelshauvers-Dery.—Contributions to the study of the Nebenkern, by Dr. E. Leclercq.

THE GOLDEN BOUGH.

The Golden Bough: a Study in Comparative Religion. By J. G. Frazer, M.A. In Two Volumes. (London: Macmillan and Co., 1890.)

THE object of this book is to offer a probable explanation of the priesthood of Nemi. The method adopted is to show that such barbarous customs as those associated with that priesthood were also carried on elsewhere; and "if we can detect the motives which led to its institution; if we can prove that these motives have operated widely, perhaps universally, in human society, producing in varied circumstances a variety of institutions specifically different but generically alike; if we can show, lastly, that these very motives, with some of their derivative institutions, were actually at work in classical antiquity; then we may fairly infer that at a remoter age the same motives gave birth to the priesthood of Nemi."

The author, Mr. Frazer, informs us in his preface that he has for some time been preparing a general work on primitive superstition and religion. We are glad to learn from the same source that his studies to this end have been systematized, encouraged, and influenced by Mr. W. Robertson Smith. The book shows from cover to cover how important this influence has been, and how thorough has been the work done; it is a perfect mine of early folk-lore, while the method of arrangement and the way in which the facts are marshalled along the different lines of inquiry, leaves nothing to be desired.

It must be understood, however, that this is not the general work to which we have referred above. It is an *excursus* on a special point, an attempt to solve the difficult problem connected with the hitherto unexplained rule of the Arician priesthood.

Having said thus much on the origin of the book, we may next proceed to remark that in such a case as this criticism pure and simple of the details is almost out of the question. We prefer rather to lay before the readers of NATURE a summary of the various steps employed in the argument, accompanied by references to those points which we have found of special interest.

The priesthood of Nemi is one of the most extraordinary character, and has no parallel in classical antiquity. The sacred grove and sanctuary of Diana Nemorensis, or Diana of the Wood, lay on the northern shore of the lake, right under the steep cliffs on which stands the modern village of Nemi. The lake and grove were sometimes called the lake and grove of Aricia, but the town of Aricia was distant three miles. There grew in this grove a certain tree, around which there might almost always be seen a strange figure prowling. The man carried a drawn sword, and persistently looked about him as if he expected every moment to be set upon by an enemy. He was the priest, and also a murderer; and "the man for whom he looked was sooner or later to murder him and hold the priesthood in his stead. Such was the rule of the sanctuary. A candidate for the priesthood could only succeed to office by slaying the priest; and having slain him he held office till he was himself slain by a stronger or a craftier."

The author begins by stating the few facts and theories bequeathed to us on the subject of the priesthood of Nemi. The first questions that he attempts to answer concern the title of this priest. Why was he called the king of the wood? Why was his office spoken of as a kingdom? To obtain an answer to the first question he has to go into the details of the facts, legends, &c., recorded of primitive man, and to see whether there were such beings as kings of rain, water, fire, &c., to match the Arician king who bore the name of king of the wood. In this search he brings out a wonderful array of interesting facts as regards sympathetic magic, rain making, sunshine making, controlling the wind, fighting the wind, &c.; and § 3, which treats of incarnate gods, is full of examples, "drawn from the beliefs and practices of rude peoples all over the world, which may suffice to prove that the savage, whether European or otherwise, fails to recognize those limitations to his power over nature which seem so obvious to us."

Having found instances of kings of rain, water, and fire, the author next looks for a king of the wood. Since the worship of trees played an important part among the religious ideas of the Aryan race in Europe, a king of the wood ought to be found closely connected with tree worship, and so it happens. Innumerable instances of this form of worship have been got together, showing the way in which trees were looked upon at an early stage of civilization. Men supposed that the trees had souls, that tree spirits could give rain and sun, and that the harvests were dependent on them. "In Sumatra, so soon as a tree is felled, a young tree is planted on the stump; and some betel and a few small coins are also placed on it. Here the purpose is unmistakable. The spirit of the tree is offered a new home in the young tree planted on the stump of the old one, and the offering of betel and money is meant to compensate him for the disturbance he has suffered." The may-pole of to-day is only an emblem of the old form of tree-worship—a survival of the belief in the fertilizing power of the tree spirit.

The author then discusses the manner in which the tree spirit is "conceived and represented as detached from the tree and clothed in human form, and even as embodied in living men and women," a great number of examples being given. He also gives instances of the double representation of the spirit of vegetation by a tree and a living man. Before concluding this chapter, the question is discussed as to whether these forms of tree-worship help to explain the priesthood of Aricia. He believes they do. "In the first place the attributes of Diana, the goddess of the Arician grove, are those of a tree spirit or sylvan deity. Her sanctuaries were in groves, indeed every grove was her sanctuary, and she is often associated with the wood-god Silvanus in inscriptions. . . . Like a tree spirit, she helped. . . . She was the patroness of wild animals. . . ." He then goes on to suggest that the king of the wood may have been, like the "king of May, the grass king, and the like, an incarnation of the tree spirit or spirit of vegetation, &c."

The next chapter, consisting of a little over 100 pages, deals with the peril of the soul. The royal and princely taboos which kings had to undergo in order to uphold their sacred character in the minds of their subjects are first described, among which we may mention the following. They were compelled to live in a state of seclusion.

Before strangers entered a district they (the strangers) had to undergo certain ceremonies, so as to be disarmed of their magical powers, which might do harm to the king. Great precaution must be observed at meals, in order that they might not be seen eating or drinking, &c. An interesting description of the Mikado's mode of life, written two hundred years ago, illustrates well some of these taboos.

A great number of instances relating to the various ideas of what the soul is and of what it can do are given. Thus, "it is a common rule with primitive people not to awaken a sleeper, because his soul is away and might not have time to get back; so if the man wakeneth without his soul he would fall sick." Some people believe a man's soul to be in his shadow, others in the reflection of his form by water; thus the "Zulus will not look into a dark pool, because they think there is a beast in it which will take away their reflections, so that they die." Very curious instances are given of people running after souls, the methods adopted for catching them, examples of the recall and recovery of souls, &c.

Chapter iii. concerns the "killing of the god." As the author showed in the preceding chapter that the divine priest or king had to undergo horrible taboos, so in this one he points out that, in consequence of the great value attached to his life, the only means of preserving it from inevitable decay necessitated a violent death. He applies this argument to the king of the wood. "He too had to be killed, in order that the divine spirit, incarnate in him, might be transferred in unabated vigour to his successor. The rule that he held office till a stronger should slay him might be supposed to secure both the preservation of his divine life in full vigour, and its transference to a suitable successor as soon as that vigour began to be impaired." In order to confirm the conjecture that the king of the wood was formerly put to death at the expiration of a set time, the author first of all finds the evidence that can be adduced of a custom of periodically killing his counterparts, the human representatives of the tree spirit. As an illustration of these we may mention that in Saxony and Thuringia there is a Whitsuntide ceremony called "chasing the wild man out of the bush," or fetching the wild man out of the wood, the tree spirit or spirit of vegetation being represented by the wild man.

The next step taken in the argument is to show that the "custom of killing the god, and the belief in his resurrection, originated, or at least existed, in the hunting and pastoral stage of society, when the slain god was an animal; and survived into the agricultural stage, when the slain god was the corn, or a human being representing the corn." To do this a great number of examples are taken into consideration; the spring customs of the European peasantry are referred to, among which the most important are known as "burying the carnival" and "driving or carrying out death." The ceremonies carried on in connection with Osiris, Adonis, Thammuz, Attis, and Dionysus by the Egyptians, Syrians, Babylonians, Phrygians, and Greeks, were similar to those in Northern and Western Europe demonstrating the death and resurrection of vegetation. We may here mention that although some writers identify Osiris with the sun, the author is inclined to treat him as a deity of vegetation. Here we fancy modern Egyptologists who are not dependent either upon Diodorus or Plutarch will join issue with him. In like manner Dionysus, though he is often conceived and represented in animal shape, is here understood to be a deity of vegetation, for "the custom of killing a god in animal form . . . belongs to a very early stage in human culture, and is apt in later times to be misunderstood. The advance of thought tends to strip the old animal and plant gods of their bestial and vegetable husk, and to leave their human attributes (which are always the kernel of the conception) as the final and sole residuum. In other words, animal and plant gods tend to become purely anthropomorphic."

In the remaining few pages of this chapter the spirit of vegetation is discussed in examples of the corn spirit; the various names given to this spirit in the different countries being the old man, the old woman, corn mother, maiden, &c. In all these cases the idea is that the spirit of the corn is driven out of the corn last cut or last threshed, and lives in the barn during the winter. Hence the idea brings us in presence of the Egyptian view that Osiris represents the latent Ra. At sowing-time he goes out again to the fields to resume his activity as an animating force among the newly sown corn.

In some cases human sacrifices were made to promote the fertility of the fields. Among many examples given is that of the Indians of Guayaquil (Ecuador), who sacrificed human blood and the hearts of men when they sowed their fields; and there are instances when the victims for these sacrifices were actually kept and fattened up in order that the crops might be good, and that their death might insure immunity from all disease and accidents.

The second volume begins with examples of the corn spirit being represented in animal forms, such as a gander, goat, hare, cat, and fox. During the course of this discussion the author connects this corn spirit in animal form with the ancient deities of vegetation—Dionysus, Demeter, Adonis, Attis, and Osiris. He first of all points out, with the help of numerous references to ancient authorities, how these deities were represented in animal form: Dionysus was represented as a goat and sometimes as a bull; Demeter as a pig, &c. He then argues that since the corn spirit was represented by animals, such as pigs, goats, &c., these animals are nothing more nor less than the corn gods in animal form.

The next point he wishes to prove is that the "custom of killing the god had been practised by peoples in the hunting, pastoral, and agricultural stages of society;" the gods whom the hunters and shepherds adored and killed were "animals pure and simple, not animals regarded as embodiments of other supernatural beings." Of the many examples given concerning this point, we will here give a short extract of the bear festival of the Ainos:—

"Towards the end of winter a young bear is caught and brought into the village. At first he is suckled by an Aino woman; afterwards he is fed on fish. When he grows so strong that he threatens to break out of the wooden cage in which he is confined, the feast is held. But it is a peculiarly striking fact that the young bear is not kept merely to furnish a good meal; rather he is regarded and honoured as a fetish or even as a sort of higher being."

A curious fact about these feasts is that at their conclusion the Ainos always apologize to their gods, saying that the bear has been treated well, only he got too strong for them to keep any longer.

Having thus shown that the custom of killing the god was practised in the hunting, pastoral, and agricultural times, the author points out another aspect of the custom, that of laying on the dying god all the accumulated misfortunes and sins of the whole people. He begins by showing us first how each individual got rid of his sins by transferring them to some person, animal, or thing; then he points out the methods adopted by the inhabitants of villages, towns, &c., for getting rid of their sins wholesale. Some used to drive them into the sea, others used to go through their own village and smash everything, so as to drive them out. Among the principal methods employed was that of the scapegoat. A goat, laden with the sins of the people, was sent out of the village. Sometimes a boat was used as a scapegoat, and sent adrift to sea, filled with provisions and branches of trees in which were placed all the sins and diseases of the people. Human beings were sometimes used as scapegoats and were sacrificed; and the employment of divine men or animals was by no means rare. Thus it appears "that human sacrifices of the sort I suppose to have prevailed at Aricia were, as a matter of fact, systematically offered on a large scale by a people whose level of culture was probably not inferior, if indeed it was not distinctly superior to that occupied by the Italian races at the early period to which the origin of the Arician priesthood must be referred. . . ."

Of the two questions asked at the commencement of this work—Why had the priest of Nemi to slay his predecessor? and Why, before doing so, had he to pluck the golden bough?—the first has been answered, and it only remains to find the answer to the second in the last chapter. The author first inquires what the golden bough was. He begins by mentioning some of the rules or taboos by which the life of the divine kings or priests is regulated, the two chief ones being that they must neither behold the sun nor touch the ground for a specified time. These taboos were intended to preserve the life of the divine person, together with the life of his subjects and worshippers, and the reason why they were suspended between heaven and earth was that their lives were then considered safe and free from any harm. In the description of the Mikado's mode of life it is stated that it would be prejudicial to his dignity and holiness to touch the ground with his feet, and that he should not expose his head to the sun, as its rays are not worthy to shine on it. During the course of this inquiry the author finds out that "these two rules—not to touch the ground and not to see the sun—are observed either separately or conjointly by girls at puberty in many parts of the world," and that they are kept in close confinement, the object of this seclusion being to neutralize "the dangerous influences which are supposed to emanate from them at such times." In these taboos the sun and earth were looked upon as media through which evils or diseases might be transferred, and in order to prevent bad consequences kings and women between certain ages had to undergo this period of isolation and confinement to minimize the chances of infection.

He next gives an account of the myth of a god, whose life "in a sense might be said to be neither in heaven nor earth, but between the two." This was the Norse Balder, the good and beautiful god, who was invulnerable, but who was eventually killed by having a piece of mistletoe thrown at him, and then burnt on a funeral pile. In this section the author traces out what he supposes to be the origin of this myth. He finds that its two main features, the pulling of the mistletoe and the burning of the god, were reproduced in the great midsummer festival of the Celts; and in Sweden there were midsummer fires, known as Balder's bale-fires, which "puts their connection with Balder beyond the reach of doubt, and makes it certain that in the former times either a living representative or an effigy of Balder must have been annually burned in them." He then remarks that "customs of this kind can be traced back on historical evidence to the middle ages, and their analogy to similar customs observed in antiquity goes with strong internal evidence to prove that their origin must be sought in a period prior to the spread of Christianity." May we not here suggest that these customs might have been carried on in the Egyptian temples, since we now know that some of them were oriented to the rising or to the setting sun at either the summer or winter solstice; and that the "manifestation of Ra" was a thing for kings to see? In fact a writer in mediæval times, as referred to on p. 258, vol. ii., "explains the custom of rolling the wheel to mean that the sun has now reached the highest point in the ecliptic and begins thenceforward to descend"; which is exactly what the temples were built for—in order to catch the first rays of the rising or the last rays of the setting sun at these times of the year.

The author then proves that at these solemn rites the fires were regularly made of oak-wood; and shows that since the connecting link of the oak with the mistletoe is given in this very myth, and that "Balder could be killed by nothing in heaven or earth except the mistletoe," then "as soon as we see that Balder was the oak the origin of the myth becomes plain." Thus it is shown that when the god had to be killed, and when the sacred tree had to be burnt, it was necessary in the first instance to break the mistletoe off the tree.

In the two following sections he deals with the "external soul in folk tales" and the "external soul in folk custom"; the former consists of examples selected with a view of illustrating both the characteristic features and the wide diffusion of this class of tales, while the latter shows us that the idea is "not a mere figment devised to adorn a tale, but is a real article of primitive faith, which has given rise to a corresponding set of customs."

In the last section we have a short general summing up, in which the author states the conclusion which he arrives at concerning this strange and recurring tragedy of the priesthood of Nemi. The priest of the Arician grove, or, as he was called, the king of the wood, personated, as we now see, the tree on which the golden bough grew. This tree most probably was the oak, so that he was the personification of the oak-tree. As an oak spirit his life and death was in the mistletoe on the oak, so that as long as the mistletoe remained intact he could not die. In order, therefore, to slay him, it was necessary to break the golden bough, or, in other words,

to cut down the mistletoe, and probably to throw it at him.

Although this work deals with an explanation of the priesthood of Nemi, yet, on the other hand, there is plenty of substance to be got out of it which might help others who are pursuing a similar line of research in other directions. It might be interesting, for instance, to know if there is any connection between the Norse god Balder and the following legend of the Druids, referred to in Flammarion's "Astronomical Myths":—

The night of November 1 was, to the Druids, one full of mystery, in which they annually celebrated the reconstruction of the world. On this day the Druidess nuns had to pull down and rebuild the roof of their temple as a symbol of the destruction and renovation of the earth. If any of these hapless nuns happened to drop any of the materials for this new roof, they were immediately pounced upon and torn to pieces by their companions, who were seized with a fanatic transport. It was also on this day, or rather on this night, that the Druids extinguished the sacred fire, and then all other fires were put out, and a primitive night reigned throughout the land. Then the phantoms of those who had died during the preceding year passed along to the west, and were carried away by boats to the judgment seat of the god of the dead.

Another point we may mention concerns the solemn festival of the Isia, which, like the corroborees of the Australians, lasted three days, and was celebrated in honour of the dead and of Osiris, the lord of the tombs. There is a curious uncertainty about the date of this festival, the author telling us that "from the fact that, when the calendar became fixed, Athyr fell in November, no inference can be drawn as to the date at which the death of Osiris was originally celebrated." Now the Egyptians paid great attention to astronomy, and it has been stated that the day this festival commenced was at the culmination of the Pleiades at midnight.

In drawing to a conclusion our notice of this most interesting study in comparative religion, we must again direct attention to the great amount of labour the author must have undertaken in order to bring before us in a logical order the examples and myths with which these volumes abound. As a book of reference it will be found most valuable, being supplemented by a good index.

W.

GOODALE'S "PHYSIOLOGICAL BOTANY."

Physiological Botany. I. Outlines of the Histology of Phænogamous Plants; II. Vegetable Physiology. By George Lincoln Goodale, A.M., M.D., Professor of Botany in Harvard University. Gray's Botanical Textbook (Sixth Edition), Vol. II. (London: Macmillan and Co., 1890.)

THE first volume of Asa Gray's "Botanical Text-book appeared in 1842, and, in its later editions, "Structural Botany" is still a valued hand-book. Prof. Goodale's "Physiological Botany" forms the second volume, and the series is to be completed by Prof. Farlow's "Introduction to Cryptogamic Botany," and by that fourth volume on the natural orders of Phanerogams which Asa Gray "hoped rather than expected" to contribute.

Prof. Goodale's volume consists of two parts—a group of chapters (192 pages) on the histology of plants, and a section of 281 pages dealing with physiology. The present notice will be confined to the latter part of the book.

The English translation of Sachs's "Vorlesungen" and Prof. Vines's excellent lectures have done much to help the English student of botanical physiology. But in such a large and growing subject we are not likely to be overdone with text-books; we were prepared to welcome a new one, and it was in no unfriendly spirit that we opened Prof. Goodale's pages. We may say at once that our hopes have been disappointed, and that, in spite of a good deal that is worthy of praise, it is far from being a satisfactory book.

A text-book may interest us in one of two ways: it may be written with the vigour and breadth which make such excellent reading of Sachs's "Experimental Physiologie," published some twenty-five years ago; or it may, without being the work of a master, earn our thanks as a repertory of well-gathered and well-handled facts. Prof. Goodale's book seems to us to possess neither qualification in a very high degree.

We are disappointed too in another way. The date on the title-page (1890) naturally led us to look for discussions on the more important points which have arisen during the last three or four years. For instance, we expected a full account of the nitrogen question, a full account of the transpiration question, and at least some account of such interesting work as that of Wortmann, Elfving, and Noll, on geotropic curvature. But these things are not to be found, for the simple reason that the author's preface is dated 1885: we think that the public may fairly ask for some indication, on the title-page, of this condition of things.

It is no doubt a difficult thing to partition out a large subject among a limited number of pages; no two men would do it in the same way, and probably no one would be quite satisfied with the manner of distribution fixed on by another. But Prof. Goodale has exceeded the limits which may be allowed to individuality. For instance, his account of geotropism is compressed into twenty-five lines,—hardly more than is given up to De Candolle's "floral clock," and not nearly so much as is allowed to an account of the hybridization of *Lilium lancifolium* and *L. auratum*. This result—namely, the production of Parkman's lily—is no doubt of interest, but it is surely of less value to the student of physiology than a full discussion of so wide-reaching a mode of growth as geotropism.

Again, in the matter of arrangement some improvement is to be desired. For instance, in chapter xii. (on vegetable growth) we pass directly from the histology of cell-division to an account of the auxanometer. Further on we come across a brief account of turgescence, but without a hint as to its importance in relation to growth. In the paragraph on tension, the author gives no idea of the biological value of the combination of forces in giving rigidity to growing parts. The series of changes known as the grand period of growth is but slightly sketched, and no one coming to the subject for the first time would have a guess at the importance of the phenomenon.

To return to what is said on geotropism. It would surely have been more in accordance with modern views

if an attempt had been made to show that geotropism, heliotropism, hydrotropism, &c., are all parts of one phenomenon: we find, however, no hint that these modes of growth are now regarded as so many different forms of reply to stimulus. Under geotropism, Knight's experiment is not even mentioned, and the student would probably never discover that gravitation *as a stimulus* had anything to do with the matter. Prof. Goodale (p. 392) believes that a negatively geotropic organ curves upwards because the "nutritive fluids" collect "in greater amount in the cells upon its lower side." In the case of positively geotropic organs he seems to believe in the ancient doctrine of plasticity, according to which a root bends down just as a tallow candle collapses in warm weather. He connects this view with the so-called absence of tension in roots; from this we should be led to suppose that he believes all roots to be positively geotropic, but this does not seem to be the case, for he says that "it is a significant fact that in the case of certain branches from roots the direction of growth is oblique."

The treatment of heliotropism is on the same level: he believes in De Candolle's exploded theory, which depends on the fact that growth is favoured by shade, and according to which the difference in illumination on the two sides of the organ is not a stimulus, but the direct cause of curvature.

In the chapter on the movements of plants the account of the clinostat is not good. Prof. Goodale omits to mention the especial merit of this instrument, viz. that it counteracts at one and the same time the effects of one-sided illumination and of the gravitation stimulus. The illustration of the clinostat is singularly unfortunate, being in fact Sachs's drawing of secondary roots bending, under the influence of centrifugal force, in Knight's experiment.

In the discussion on circumnutation it is a pity that no allusion is made to Wiesner's careful critique on the "Power of Movement in Plants." In the same way a modern account of twining plants should give references to Baranetzky's and Wortmann's papers.

Chapter ix., on the "Transfer of Water," is an improvement; still the heart of the matter is hardly touched, and the student who relies on this discussion will be but indifferently instructed. He will not, for instance, have any clear idea that the question whether or no the transpiration-current travels as water of imbibition is or ever was a problem deserving of especial attention.

Further on we find De Vries's experiments on the withering of stems cut in air, and on their preservation from withering when cut under water, but without any reference to von Höhnel's work on negative pressure, which has such important bearings on this point, and indeed on the whole question of water-transfer. In the section on the mechanism of stomata we miss the names of Schwendener and Leitgeb; and under the heading "Relation of Age of Leaves to Transpiration," there is no clear explanation of the relations of stomatal and cuticular transpiration.

In chapter x. a very fair account is given of the assimilation of carbon. The author deserves credit for giving the passage in which, in 1817, the word *chlorophyll* was proposed; just as in another part of the book he gives the passage in which the term *protoplasm* was first employed. With regard to chlorophyll we think it a pity that any encouragement should be given to the confusion between chlorophyll and chloroplasts by such a remark as the following: "The term chlorophyll originally applied to the pigment rather than to the substance which contains it, is now used indifferently to denote the coloring-matter and the portions of protoplasmic mass which are tinged by it." This statement is all the more unnecessary because he gives on the next page a useful table of the plastid-nomenclature of Schimper, Meyer, &c. Pringsheim's hypochlorin theories are reproduced, but without the word of warning that should accompany such speculations in a book intended for students.

There is a fair account of Timiriazeff's and of Engelmann's work on assimilation; but we doubt whether it would induce the beginner to appreciate the extraordinary interest and importance of Engelmann's researches. The section ends with an outline of the "early history" of assimilation, which contains some interesting quotations from Priestley and Ingenhousz.

The section on the "Appropriation of Nitrogen" suffers grievously from the fact that the nutrition of Fungi is left out of account. The "Synthesis of Albuminous Matter" is inadequately treated, and the same must unfortunately be said of the action of ferments; and with regard to the origin of alkaloids it would have been better to have given the well-known hypothesis that they are waste products, rather than to have left their meaning in complete obscurity.

Chapter xiv. is devoted to reproduction: the author seems to have been hampered with the fear of overlapping the forthcoming book on Cryptogams, as he confines himself almost entirely to the higher plants. He gives, in a footnote, some account of the reproduction of Spirogyra, Fucus, Nemalion, Funaria, Pteris, and Selaginella, but gives no idea of the connection between this latter form and the Spermaphytes. It is clear that without a free use of the lower forms it is impossible to give such a generalized view of the reproduction of plants as is appropriate in a physiological text-book.

In discussing the colours of flowers, it would have surely been better to have given H. Müller's interesting generalizations in place of the barren statistics of Kohler and Schübeler. The chapter concludes with some useful facts on hybridization.

The last chapter in the book consists of a few pages on germination. The greater part of this discussion might with advantage have been divided among those parts of the book which deal with the general conditions of plant life and with metabolism. Of the interesting growth-phenomena of germination, such as the protrusion of the radicle, the manner in which the cotyledons are freed from the seed-coats, &c., some account should have been given, even at the risk of overlapping vol. i. of the Text-book.

In spite of a general faultiness of the kind indicated the book is not without value. It is clearly written, and contains the substance of a large number of books and papers, references to which are given at the foot of the page (instead of at the end of the chapters) to the very great convenience of the reader. Many of these references to older papers are likely to be useful, and of salutary effect on the rising generation of botanists, who are somewhat inclined to overlook the work done in the days of their grandfathers.

The author deserves credit for his appendix, in which a series of simple physiological experiments are described, with a view to their repetition by the student.

FRANCIS DARWIN.

OUR BOOK SHELF.

Plant Organization: a Review of the Structure and Morphology of Plants by the written method. By R. Halsted Ward. (Boston, U.S.A.: Ginn and Co., 1890.)

THIS is nothing more than a series of blank charts, intended for students to fill in with the details of plant descriptions. The charts are prefaced by a few pages of letterpress, wherein are contained some of the author's views on plant morphology, together with general hints and a summary of the terminology to be used. We cannot say that the author's attempt to simplify the technical terms ordinarily made use of in descriptive work is altogether a success. For instance, the words "shingled" and "straddling" for *imbricate* and *equitant*, will hardly recommend themselves to teachers on this side of the Atlantic; nor are plants either epiphytic or parasitic on *rocks*. As to the blank charts which constitute the feature of the book, it can only be said that, as such things go, they are entirely praiseworthy. But are charts of this kind really necessary? A child just beginning the subject may profitably make use of the very simple schedules devised by the late Prof. Henslow; but by the time he has advanced so far as to be able to use these complicated and detailed ones, drawn up by Mr. Ward, we think he will do much better without being kept in leading-strings. The advantage gained by writing descriptions will be vastly enhanced if he be now permitted to think a little for himself.

F. W. O.

Geometrical Conics. Part I. The Parabola. By Rev. J. J. Milne, M.A., and R. F. Davis, M.A. (London: Macmillan and Co., 1890.)

IN this work a departure is made from the general order of the propositions adopted by most geometrical writers "so as to bring the argument into closer agreement with that found in analytical text-books, in order that both methods may be studied side by side." Instead of a series of detached propositions, the authors have made a continuous treatise, and by this means have been able to deal with some of the more important points more fully than they otherwise could have done.

This part, which treats of problems and theorems relating only to the parabola, is thoroughly well done, and contains many problems fully worked out which are absent from other similar books.

Those reading the subject for the first time ought to have no difficulty in grasping the various propositions and theorems, and at the end numerous examples on them, with hints and solutions, are added.

Short Logarithms and other Tables. By W. Cawthorne Unwin, F.R.S. Fourth Edition. (London: E. and F. N. Spon and Co., 1890.)

THE short tables given in this book will be found to serve the purpose for which they were intended, which is to facilitate practical calculations and to solve arithmetical problems in a very complete way. The logarithmetic table is very short, but, if used properly, the error need not exceed one per thousand; logarithms of three-figure numbers to 999, and of four-figure numbers to 2000, are given.

Amongst the other tables are: anti-logarithms, natural and logarithmetic trigonometric functions, functions of numbers, product of numbers, table of weights and measures, and conversion tables for English and metric measures. The last-named table is inserted specially for the use of engineers, as so many treatises on engineering are now being published in France and Germany in which the measures are given according to the metric system, and in consequence of which constants for the quick conversion of these measures are required.

W.

Elementary Algebra. By Charles Smith, M.A. (London: Macmillan and Co., 1890.)

THIS is a second edition of this well-known book, and differs from the first in some important particulars. It has been thoroughly revised, and the early chapters have been simplified and remodelled. Chapters on logarithms and scales of notation form a useful and valuable addition, and there is a great increase in the number of the examples. For beginners this work should prove invaluable, and even more advanced students would do well to glance over its pages.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

British Association Procedure.

I SHOULD be sorry if Prof. Lodge or anyone else should suspect me of a desire to interfere with the opportunities which are afforded by meetings of the British Association for friendly intercourse between workers, and especially between the younger scientific men and their seniors, for I feel that those opportunities constitute one of the chief advantages of attending the meetings. But with the desire to avoid waste of time in merely journal business I should prefer that each Sectional Committee should be reduced to a small executive body to whom could be entrusted the task of arranging the programme for each day, and in a preliminary way other business, such as the selection of committees to carry out suggested new researches. The appointment of such Committees and the other business would be accomplished quickly enough at a meeting of the whole Section, and then opportunity would be given to all the members for expressing an opinion or offering suggestions. The plan at present adopted is neither one thing nor the other. The Sectional Committees are too large for the despatch of business, and yet may not include every desirable member of the Section. The demand for election to which I referred comes from a certain class of people whose single purpose is served when they get their names printed on the list.

I happen to have by me the journals of the Birmingham meeting, and the number of names on the Committees of the first three Sections I find as follows:—

	Section A	B	C
Vice-Presidents	6	9	7
Secretaries	4	5	4
Committee	52	51	93
Totals	62	65	104

When numbers like this are reached why pretend to draw a line at all?

WILLIAM A. TILDEN.

Birmingham, September 23.

The Exploration of Central Asia.

THE late notice in NATURE of August 14 (p. 378) with reference to the work of exploration now being carried out by the Russians around Kashgar, and that M. Grombchevsky, having received permission and funds to continue his work, was starting for Rudok, is not pleasant reading for Englishmen who know that part of the Himalayas. Rudok is a small place with a fort and Gonpa or monastery, and gives the name to the tract of country lying at the eastern end of the great Pangkong Lake, on the very confines of the territory of the Kashmir State. In 1863 I carried the survey up to that extreme eastern limit, and succeeded by avoiding observation in getting within a very few

miles of Rudok itself. The news was soon conveyed there, and the Governor, a native of Lhassa, came out to meet me. He brought presents of tea, sheep, and goats, and was most civil, but begged that I would go back, as he would lose his appointment and be disgraced if it became known that he permitted me to advance further. His politeness disarmed opposition, and my orders, given in writing, were not to get into collision with the Tibetans. We drank a good deal of tea, made in their mode churned with butter and salt, which was always simmering in his tent, and I managed to persuade him to let me ascend a conspicuous peak a few miles further on, and from which I obtained a magnificent panorama of the lake-dotted plain to the eastward of Rudok. We parted excellent friends, and I presented him with a single-barrelled pistol, in return for the presents he had given us. I feel sure that had I been able to get back there the following year, I could, starting from other points, have got very much further to the eastward, and returned again *viâ* Rudok itself. I was, however, sent to another and equally interesting part of the Himalayas.

This country of Rudok is now, in 1890, to be visited, examined, and reported upon by the Russians. Twenty-seven years have gone by since I was on its very threshold. In the interval we have had political officers appointed Residents in Leh, we have seen many journeys made by English officers and English traders to Yarkand, and yet no one has penetrated into Rudok and all that unknown country on the north and north-east which is much nearer. It does not say much for our British energy that a Russian is now to enter this area, and is now perhaps surveying within almost, I may say, a stone's-throw of our own border, which we have made no attempt to get into and know. Perhaps M. Grombchevsky may not succeed, perhaps he may lose his life, but that does not detract from the activity and devotion the Russians are at present giving to the exploration of Central Asia down to the Himalayan chain, or prevent their doing so. If they from their base can do this, why can we not ourselves? We have been content to send in natives of India, but this is not the same thing as sending European officers, for in one case the information obtained is purely topographical, no actual knowledge of physical features is gained, nothing from a military point of view, and no personal acquaintance is made with the people which might be of political or other advantage hereafter. Proceeding to the north-west of Ladak, where the Russians have lately been exploring, it appears extraordinary, with the knowledge the Government of India possessed of the vast system of glaciers of the Mustakh, south of the main range, that no attempt has been made during the past twenty-five years to finish that tract of country, and map the glaciers which descend on the north or Yarkand side, and trace the rivers flowing from them, which would be easy to accomplish, and with little or no danger of interruption. This I consider would be of far more importance and of infinitely greater interest scientifically than spending thousands of rupees on large-scale surveys of Indian hill stations and cantonments, or the resurvey of parts we know well on larger scales.

Although the Indian Survey and the Quarter-Master-General's department have made us acquainted with vast tracts of country, yet much more might have been explored if persistent efforts of every kind, along the line of the Himalayas from Kashmir to Assam had been made during the past thirty years, and if the Government of India had given encouragement to officers who were able to survey and to make the most of their opportunities to do so. I can remember when many such good opportunities have been lost, owing to a contrary policy, for fit men ready to go have not been wanting; also, when such opportunities have been taken, and at a time when the Government would not have given their sanction had it been applied for, as, for instance, when Mr. Johnstone, an uncovenanted assistant of the Kashmir Survey party proceeded to Yarkand alone, and returned in safety in 1864, bringing back a large addition to the then complete blank of intervening country, and fixing with some exactitude the position of the large cities he visited. We thus have left and are leaving to Russian subjects, who have the good wishes and countenance of their Government, to survey tracts of country lying upon our line of frontier, and we shall probably see them the first of European nations to plant their feet in Lhassa. They go to work on the right system, for much more can be done by single individuals in a quiet way, with a few carriers and attendants, than by organizing large unwieldy missions, with a little army of camp-followers and sepoys, such as it was proposed to send from Darjiling some few years ago. Such preparations become magnified into an army with aggressive aims, certain to arouse political difficulties; it is a burden on the resources of the country it has to pass through, and the possibility of misunderstandings and quarrels arising over the collection of and payment for the same.

We might have been working for years past to the northward, in many directions, by small exploring parties, and have now possessed an intimate knowledge of the physical features of the country, and its zoology, fauna, and flora, such as the Russians do in their thorough manner, but which our Government appears not to understand the value of, eminently unscientific as it is. After all, disagreeable though it be to see opportunities lost, those who do appreciate scientific methods of work must thank Russian explorers, such as Prejevalsky, and now Grombchevsky, for the light they have, in the last few years, thrown on the geography and natural history of Central Asia, from Siberia south towards British India. H. H. G-A.

Variability in the Number of Follicles in Caltha.

IT is easy to understand, supposing a tendency to variability, that characters of little value (as the colours of certain domesticated animals) might vary considerably, because not kept in check by natural selection. If it does not matter to a species whether it is unicolorous or spotted, for instance, one can see how both varieties may coexist without any tendency to the formation of a new species, and it might be rather an advantage than otherwise that individuals should differ from one another. But those parts connected with so important a function as the reproduction of the species would, one might suppose, be rigidly guarded over by the survival of the fittest, and any great variability in the number of offspring would hardly be expected within the limits of a species.

That such variability exists, however, we have abundant proof. The variability in the number of follicles in the Ranunculaceæ is astonishing. Coulter ("Manual of Botany of Rocky Mountain Region") gives the pods of *Caltha* as from 5 to 12; but this does not nearly represent the amount of variation. *Caltha leptosepala*, DC., is very abundant at West Cliff, Colorado, and this year I examined a number of specimens of the flowers, and counted the follicles, with the following result:—

Follicles.	Specimens.
2	1
3	7
4	4
5	11
6	3
7	11
8	10
9	7
10	4
11	5
12	1
13	5
14	3
15	1
Total	73

It thus appears that 73 flowers presented as many as 14 variations in the number of follicles, and curiously, the odd numbers are more numerous than the even, in the proportion of 47 to 26.

Miss Lowther and Miss Byington, of West Cliff, were good enough to search for variations other than those tabulated above, and they succeeded in finding specimens with 1, 18, 23, and 25 follicles respectively. T. D. A. COCKERELL.

3 Fairfax Road, Bedford Park, Chiswick, W., September 16.

The Origin of Mélinite and Lyddite.

(Picric Acid.)

IN your issue of the 4th inst. (p. 444) there occurs the following sentence:—

"Although picric acid compounds were long since experimented with as explosive agents, it was not until a very serious accident occurred, in 1887, at some works near Manchester, where the dye had been for some time manufactured, that public attention was directed in England to the powerfully explosive nature of this substance itself."

As this sentence forms part of this year's great annual scientific manifesto, with which Presidents of the British Association for the Advancement of Science are wont to favour your readers, I trust your love of scientific precision will help me to point out that, "*prior*" to the very serious accident near Manchester, public attention "*was*" directed in England to the powerfully explosive nature of this substance itself through the medium of a very serious publication in London, or rather through the medium of two very serious publications—viz. a patent and a paper read before the Chemical Society, as you will see from the following statement,[1] which I drew up last spring at the request of and, as I hoped, for the use of my distinguished fellow-inventor, the President of the Government Committee on Explosives, and now President of the British Association for the Advancement of Science. H. SPRENGEL.

54 Denbigh Street, S.W., September 13.

A Recently Established Bird Migration.

BURIED in the heart of a newspaper article of the 4th inst., on incorporated Worthing, is a statement which, if it may be relied on, seems to me of curious, if not unique, interest, inasmuch as it dates very closely what seems now an annual migration of birds. After speaking of West Tarring as dividing with Lancing the title of the capital of English Figland, the journalist (*Daily Telegraph*, September 4) goes on to say, "There it was that Thomas A'Becket planted the first slip—now a mouldering stump—whence, it is said, all these shady alleys, redolent of syrupy sweetness, derive their origin. There is no handsomer shrub-tree than the fig, spreading forth its many-veined, broad leaves in grateful shade, while the fruit, varying from juicy green acorns to great purple bulbs—I bought some yesterday four inches in length—peer boldly forth from every available twig. Even that discriminating bird, the Italian beccafico, has become aware, in some mysterious way, of the existence of the Worthing fig-gardens, and comes over to spend a pleasant six weeks among them, just as we go for change of air to Switzerland or the Black Forest. This is the time for his arrival, and if I may judge by certain well-picked figs on the Tarring trees, I should say that he had taken up his quarters somewhere in the immediate vicinity of the noble thirteenth century church."

We may reasonably allow a century or so from the time of Henry II., before the fig-tree would be sufficiently acclimatized and established at Worthing to attract such visitors. And then, always supposing that it is the Italian beccafico (*Motacilla curruca*, Linn.) which comes, it seems probable that he follows fig-harvest along the Riviera, and up from Southern to Northern France; though how so delicate and toothsome a mouthful manages to run the gauntlet of the continual potting which almost exterminates bird life over great breadths of that long journey is more difficult to understand. And then is it possible that a bold spirit of adventure, rather than any well-grounded certainty of knowledge, led the first comers across the Channel? Because it is a strange fact vouched for by more than one observer, and which goes dead against the old unerring instinct theory, that occasionally in the autumn migration, long streams of our emigrants make boldly out to sea from our westernmost coast where there is no land nearer than the east coast of America, and the whole flight must needs perish.

But as this whole question of bird migration is still one of the most dimly-lighted regions in the whole arcana of natural history, and its beginnings in most cases go far back into immemorial time, I trust—despite the great demands just now of the British Association reports on your valuable space—that you will kindly give some competent ornithologist, resident at, or a visitor to Worthing, the opportunity of confirming, if the fact is so, that the Italian fig-pecker has formed the habit of attending fig ripening there since the time of Thomas A'Becket.

HENRY CECIL.

Bregner, Bournemouth, September 9.

The Common Sole.

MR. CUNNINGHAM, in his valuable "Treatise on the Common Sole," recently published, remarks (p. 125), "Why I have failed to obtain soles in the first year of their growth, after the stage of those found at Mevagissey in May, I cannot understand." It may be of interest to those who are studying this subject to know that, among the investigations organized by the Royal Dublin Society, and intrusted to my care on board the s.s. *Fingal* off the west of Ireland, during the past summer, the working out of the life-history of sea fish took a prominent place.

In August, soles born in February and March were not found in shallow water, though careful search was made for them. Outside 50 fathoms we began to meet them. In 80 fathoms we took them in abundance, and also found them in the stomachs of other fish captured by the trawl in similar depths.

WILLIAM SPOTSWOOD GREEN,
H.M. Inspector of Irish Fisheries.

Dublin Castle, September 22.

A Meteor.

AT about 7.49 p.m. on the 14th inst., I saw from the garden of the Pavilion Hotel, Folkestone, an unusually large and bright meteor descend towards the north-west point of the horizon. The long and full tail left behind, like that of a large rocket, enabled one to trace its path, which at its highest point was about 6° or 8° north of Arcturus. The meteor, which was very much larger apparently than Jupiter, descended very slowly along a slightly wavy line of a mean inclination of about 75° to the horizon. The end of its path was hidden by houses on the "Bayle." J. PARNELL.

Pavilion Hotel, Folkestone, September 19.

THE WHITE RHINOCEROS.

WRITING of his sporting adventures on the River Se-whoi-whoi (a confluent of the Umniati) in Southern Mashuna-land, Mr. F. Selous, in the *Field* of August 16, says as follows:—

"It was within a mile of this spot that, two years previously [*i.e.* in 1883], I shot two white rhinoceroses (*Rhinoceros simus*), the last of their kind that have been killed (and, perhaps, that *ever will be killed*) by an Englishman. They were male and female, and I preserved the skin of the head and the skull of the former for the South African Museum in Cape Town, where they now are. I shall never cease to regret that I did not preserve the entire skeleton for our own splendid Museum of Natural History at South Kensington; but when I shot the animal I made sure I should get finer specimens later on in the season. However, one thing and another prevented my visiting the one spot of the country where I knew that a few were still to be found, and now those few have almost, if not quite all, been killed; and, to the best of my belief, the great white, or square-mouthed, rhinoceros, the largest of modern terrestrial mammals after the elephant, is on the very verge of extinction, and in the next year or two will become absolutely extinct. If in the near future some student of natural history should wish to know what this extinct beast really was like, he will find nothing in all the museums of Europe and America to enlighten him upon the subject but some half-dozen skulls and a goodly number of the anterior horns."

The skin of the head of the male white rhinoceros shot by Mr. Selous on the occasion spoken of above was forwarded by the authorities of the South African Museum to Mr. E. Gerrard, Jun., of Camden Town, to be mounted for their collection. Mr. Gerrard, knowing the rarity of specimens of this animal, was kind enough to allow the mounted head to be exhibited at a meeting of the Zoological Society of London in 1886, along with a corresponding head of the (so-called) black rhinoceros (*R. bicornis*), so that an easy comparison might be made between them.

The differences between the external forms of the heads of the two African rhinoceroses, though not, perhaps, so striking as the well-known differences in their skulls, are sufficiently obvious on comparison. I will venture to point them out in the pages of NATURE, in the hope that the attention of the several exploring parties now traversing Mashuna-land and Matabeli-land may be called to this subject, and that, in case of a straggling

[1] We have not considered it necessary to print this statement.—ED.

survivor of the white rhinoceros being met with, it may be carefully preserved for the National Collection at South Kensington.

As will be seen by the outline drawings of the heads,[1] the points by which this part of the two animals may be distinguished present themselves very appreciably. In the first place, as is already well known, the "white" mouthed" rhinoceros (as it is much better called) is distinguished by its short upper lip. In *R. bicornis* the central portion of the upper lip is far extended, and forms a quasi-prehensile organ. This is sufficiently manifest in the drawing, but may be still better seen in the living example of the same animal now in the Zoological Society's Gardens.

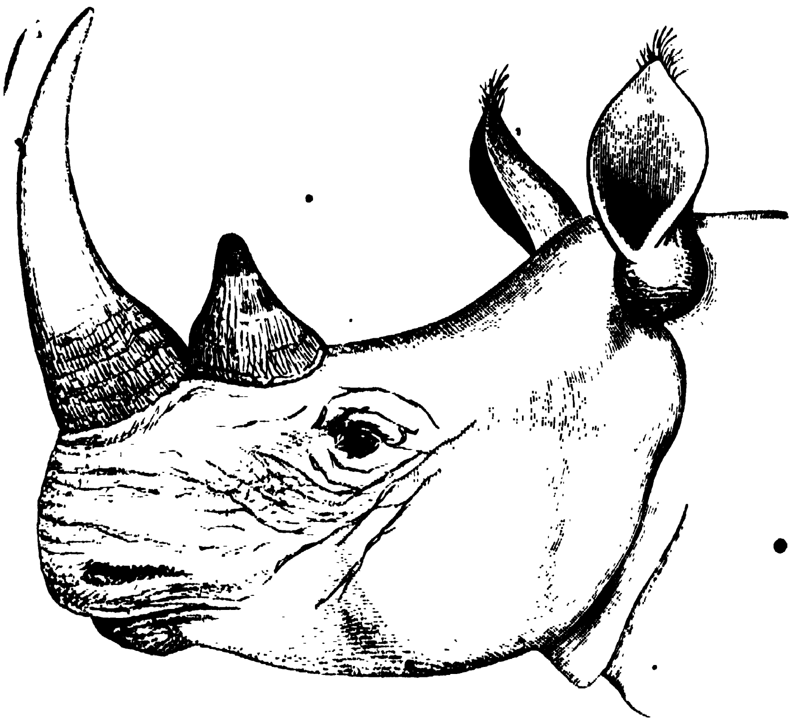

FIG. 1.—Head of *Rhinoceros simus*.

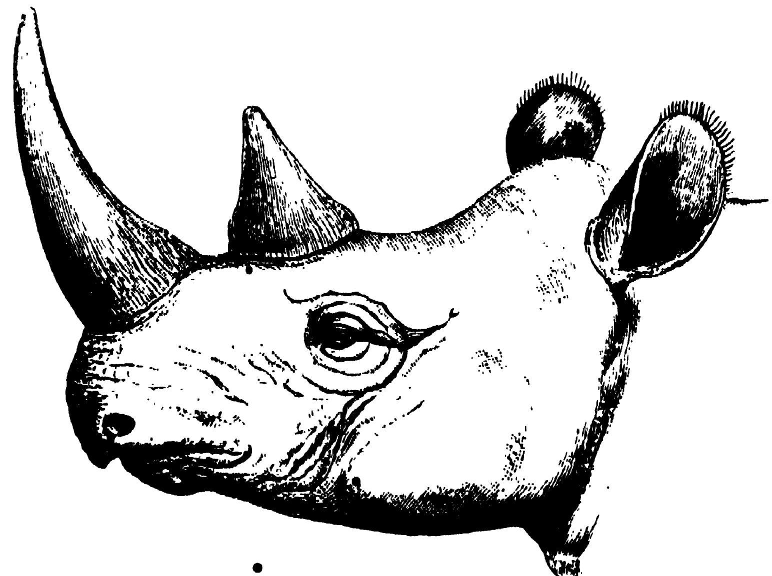

FIG. 2.—Head of *R. bicornis*.

A second point in which the heads of the two African rhinoceroses differ materially is in the size and shape of the ears. In *R. bicornis* (Fig. 2) the ear-conch is much rounded at its extremity, and edged by a fringe of short black hairs which spring from the margin. In *R. simus* (Fig. 1) the ear-conch is much more elongated and sharply pointed at its upper extremity, where the hairs which clothe its margin constitute a slight tuft. While the upper portion of the ear-conch is much more expanded in *R. simus* (than in *R. bicornis*), in the lower portion the two margins are united together for a much greater extent, and form a closed cylinder which rises about 3 inches above the base.

[1] Reduced from P.Z.S., 1886, Pl. xvi.

A third point in which the two species appear to differ is in the shape of the nostrils, which in *R. simus* are elongated in a direction parallel with the mouth, while in *R. bicornis* they are more nearly of a circular shape. Again, the eye in *R. simus* appears to be placed further back in the head than in *R. bicornis*.

In conclusion, I wish to call special attention to what Mr. Selous has already said—that no museum in Europe or America possesses a specimen of this huge animal, and to point out that the country, in which alone (as is possible but by no means certain) the last stragglers exist, being now within the British Empire, it is clearly our duty to endeavour to obtain and preserve examples of the great white or square-mouthed rhinoceros for the use and information of posterity.

P. L. SCLATER.

RECENT RESEARCH AMONG FOSSIL PLANTS.

AN instructive *résumé* of recent work among fossil plants is given by the Marquis de Saporta in the *Revue générale de Botanique*, vol. ii., 1890. It appears that mosses were almost certainly represented in the Palæozoics, a species allied to Polytrichum having been discovered at Commentry, in France. Rarely as the fructification of ferns is preserved in the Coal-measures, twenty species are now investigated, confirming the view that the Palæozoic species differed widely from the present. Half of them are most nearly related to the Marattiaceæ, whilst others show affinities with the Osmundaceæ, Gleicheniaceæ, and Hymenophyllum, the vast order of Polypodiaceæ, and the Cyatheæ being unrepresented. Among the most striking discoveries in the Coal-measures is a fern trunk several yards in length, with its fronds attached. The view that the Calamarias were in part Gymnosperms is all but universally abandoned, and the close affinity of the Lepidodendrons and Sigillarias and their cryptogamic nature everywhere admitted, so that a long controversy is ended, and the truth of Prof. Williamson's contentions definitely established. Links in the chain of evolution between Cryptogams and Gymnosperms still elude our search, and the earliest vegetation of which we have any complete knowledge already presents well-developed Gymnosperms in the shape of the deciduous Cordaïtes, a few Cycads and obscure Taxads allied to Ginkgo. At the same time, we get rid of the very puzzling Spirangium, so often regarded as a possible Palæozoic Angiosperm, but now relegated by MM. Renault and Zeiller to the animal kingdom as the egg of some member of the shark family.

Under the apparently totally dissimilar climatic conditions of the Mesozoic, the overgrown luxuriant vegetation of the coal period is replaced by forests of dry scale-leaved Coniferæ, with undergrowths of small-leaved ferns and Cycads. Fructification shows the presence of Cycadeæ in the infra-Lias, and Polypodieæ in the mid-Jurassic. The researches of Count Solms into the organization of the obscure and extinct Cycad Bennettites, bid fair to clear up another important and hitherto insoluble problem—the true botanical position of Williamsonia. Work in the past year or so has been destructive to a great deal of even recent literature on the geological history of plant evolution, the foundations of all speculative writing on this subject having as yet proved most treacherous sand.

The first appearance of Dicotyledons, once supposed

to coincide with the Tertiary period, is pushed back farther and farther into the Secondary; a flora in the United States, otherwise Jurassic in facies, containing no less than seventy-five species, or more than 20 per cent. of Phanerogams, according to Lester Ward. In England the mysterious Wealden, which from analogy should preserve rich fossil floras shedding light on the origin of Angiosperms, yields little but tubers and stems of Equisetum, scraps of ferns and conifers, and a unique liliaceous stem; while our Greensands, Gault, and Chalk afford little or nothing from which the existence of flowering plants during their deposition could be inferred. The veil which has proved absolutely impenetrable in our country, and has so long enshrouded the dawn of dicotyledonous vegetation, seems, however, about to be lifted, and we wait with the utmost interest the publication of the infra-Cretaceous floras of the Potomac by Prof. Fontaine, and of the oldest European Dicotyledons, from the beds of Gault age in Portugal, by Saporta. Though, however, the forms will be revealed, a long time must probably elapse before we can hope to rightly interpret them. J. Starkie Gardner.

ON THE INFLUENCE OF HEAT ON COPPER POTASSIUM CHLORIDE AND ITS SATURATED SOLUTION.[1]

The blue crystals of copper potassium chloride, $CuCl_2.2KCl.2H_2O$, when heated to upwards of 100°, change their colour, and a closer investigation proves such is due to the formation of a new brown salt, $CuCl_2.KCl$, according to the equation—

$$CuCl_2.2KCl.2H_2O = CuCl_2.KCl + KCl + 2H_2O.$$

This same new substance can be obtained at lower temperatures, on heating the blue double salt in presence of copper chloride; it then results according to the following symbols—

$$CuCl_2.2KCl.2H_2O + CuCl_2.2H_2O = 2CuCl_2.KCl + 4H_2O.$$

Both transformations are reversible—*i.e.* the primitive substances are obtained anew on cooling, and both take place at definite temperatures, 93° and 56° respectively, which temperatures can be accurately determined in studying the abrupt change of volume which accompanies that of chemical composition.

The temperatures of 56° and 93° are, moreover, characterized by an intersection of three curves of solubility in each case, viz.—

1. At 56° the following three will meet—

(*a*) That of the system $CuCl_2.2KCl.2H_2O$; $CuCl_2.2H_2O$.
(*b*) That of the system $CuCl_2.2KCl.2H_2O$; $CuCl_2.KCl$.
(*c*) That of the system $CuCl_2.KCl$; $CuCl_2.2H_2O$.

2. At 93°—

(*a*) That of the system $CuCl_2.2KCl.2H_2O$; ClK.
(*b*) That of the system $CuCl_2.2KCl.2H_2O$; $CuCl_2.KCl$.
(*c*) That of the system $CuCl_2KCl$; ClK.

Lastly, those same temperatures are characterized also by an intersection of four vapour pressure lines at each, viz.—

1. At 56° those of the above-mentioned three saturated solutions, and that of the dry blue salt, mixed with copper chloride, meet.

2. At 93° those of the other three mentioned above and that of the dry blue salt, mixed with potassium chloride. J. H. Van't Hoff.

[1] Abstract of a paper read at the Leeds meeting of the British Association.

THOMAS CARNELLEY.

By the death of Prof. Carnelley the science of chemistry in this country has suffered an irreparable loss. It appears that some little time ago Dr. Carnelley had been suffering from an attack of influenza, and it was whilst returning to Aberdeen after a journey to the south, made with the object of recruiting his health, that he was seized with sudden and severe illness, which was due, as his medical attendants discovered, to the formation of an internal abscess. Surgical aid proved unavailing, the patient's strength gradually gave way, and Dr. Carnelley passed away at mid-day of August 27, at the comparatively early age of thirty-eight.

Prof. Carnelley was a native of Manchester, the son of Mr. William Carnelley, Chairman of the directors of Messrs. Rylands, Limited, of that city. His early education was received at King's College School, London, and it was during this period, whilst attending the evening classes at King's College, that Carnelley began the study of that science with which he in after life identified himself. In 1868 he entered the Owens College, Manchester, gaining one of the Dalton Entrance Mathematical Exhibitions. During his career as a student, an exceptionally brilliant one, he busied himself not only with the study of the many subjects required of graduates in science of the London University, but found time to devote special attention to his favourite science, and carried out an original investigation on the vanadates of thallium, for which he received in 1872 the Dalton Chemical Scholarship. In this year also he obtained the degree of Bachelor of Science of the University of London, gaining at the final examination for this degree marks qualifying for the scholarship in chemistry, in consequence of which he held the Dalton Chemical Scholarship for an additional year. During the next two years he acted as private assistant to Prof. Roscoe, and commenced his career as a teacher by giving lectures in connection with the evening classes of the Owens College. During the year 1874-75 he continued his studies at the University of Bonn under Profs. Kekulé, Zincke, and Wallach; and on his return to England in 1875 was appointed Demonstrator and Assistant-Lecturer in Chemistry in the Owens College under Prof. Roscoe. During the time that he held this appointment he also acted as Principal of the North Staffordshire School of Science at Hanley, where his teaching proved eminently successful. In 1879 Carnelley, who had taken the London degree of D.Sc., was appointed to the newly-founded chair of chemistry in the Firth College, Sheffield, and, after three years' successful work in this institution in fitting up the chemical laboratory and inaugurating the teaching of chemistry in this College, he passed on to the then recently endowed University College of Dundee. Here ample means were placed at his disposal, and he had the satisfaction of superintending the erection of a block of buildings in which are located the chemical laboratories, lecture-rooms, &c., which he had designed and carefully planned. Under his guidance the Chemical Department of the Dundee College rapidly developed; his enthusiasm, his forgetfulness of self, his unstinted energy, and his ability and zeal as a teacher, all combined to make his department the most important one in the new College and to endear him to his students. Signally successful as was Carnelley's career in Dundee as a professor of chemistry, he also in many other ways conferred lasting benefits on the town and its inhabitants, amongst whom he spent six years, perhaps the most active of his life, and his acceptance of the appointment to the chair of chemistry at the University of Aberdeen in 1888 caused universal regret in Dundee.

Amidst his many duties, first at Owens College, then at Firth College, and afterwards at University College, Dundee, where he conducted both day and evening

classes and superintended the teaching in the laboratories, Dr. Carnelley did not forget that the first duty of a man of science is to advance his subject. That he did so with good effect is seen from the numerous communications of importance contributed to the various learned societies both in this country and in Germany, either alone or in conjunction with other investigators. Prominent amongst the researches with the results of which he has enriched science are those by which he sought to extend the application of Mendeléeff's discovery of the "periodic law," in accordance with which the chemical and physical properties of the elements and of their compounds are periodic functions of the atomic weights of the elements. Carnelley, when a student at the Owens College, appears to have been greatly impressed with Mendeléeff's conceptions, and it was to the study of the physical properties of the elements and their compounds, and to the devising of new methods of obtaining trustworthy determinations of the melting-points of metallic salts and the elements, that he early devoted his energies. The results of these experiments were subsequently utilized to show that the fusibility of the elements and of certain of their compounds is a periodic function of their atomic weights. From the relationships discovered by him to exist between the melting-points of the chlorides of the elements and the atomic weights of those elements Carnelley was led to draw conclusions respecting the atomic weight of the element beryllium and to fix its position in the classification of the elements.

Other physical properties have been shown by Carnelley to be related to the atomic weights of the elements, and in a paper read at the Aberdeen meeting of the British Association he developed a series of analogies between the elements and various series of hydrocarbons, from which he concluded that the chemical elements may be represented by a formula $A_n B_{2n+(2-x)}$, in which n is the series and x the group to which the element belongs; $A = 12$ and $B = -2$. In a paper published in the *Philosophical Magazine* in January last, he tells us that since 1872 he had attempted to give the periodic law a simple numerical expression, and states that early in the summer of 1889 he had obtained such an expression, in which the atomic weight is represented as equivalent to the product of a constant, c, into a factor made up of m, a member of an arithmetical progression, dependent on the series to which the element belongs, and v, the maximum valency, or the number of the group of which the element is a member. Thus—

$$A = c\left(m + v^{\frac{1}{x}}\right).$$

The best results are obtained when $x = 2$, and m is 0 for series II., 2½ for III., 5 for IV., 8½ for V., 12 for VI., 15½ for VII., 19 for IX., 22½ for X., 26 for XI., and 29½ for XII.

The formula thus becomes $A = c(m + \sqrt{v})$, and m is a member of an arithmetical series in which the difference is 3½, save in the first two series, when it is 2½. By using this equation, the value for c in the case of 55 elements is found to lie between 6·0 and 7·2, with a mean value of 6·64. Accepting 6·6 as the value of c, the calculated atomic weight of sodium, for example, would be found as follows:—Sodium is the first member of series III., m is therefore 2·5 and $v = 1$, so that $A = 6{\cdot}6(2{\cdot}5 + \sqrt{1}) = 23{\cdot}1$. In the paper referred to the atomic weights of all the elements are given as calculated by this formula, and compared with those generally accepted. The results obtained exhibit very near approximation, the calculated values being, in fact, nearer the experimental numbers than those obtained by the aid of Dulong and Petit's law. The remarkable coincidence that the value 6·6 for the constant c in the above formula very nearly approximates to the value 6·4, accepted as the atomic heat of the elements, in accordance with Dulong and Petit's law, is noted, and that the specific heats of the elements may consequently be represented as equivalent to $\frac{1}{m + \sqrt{v}}$. The specific heats calculated by the aid of this formula are compared with the experimental values, and in the case of the 55 elements, in which a comparison can be instituted in 45 instances the agreement is very satisfactory, while the other 10 are elements the specific heats of which, according to Dulong and Petit's law, are more or less abnormal.

Accepting Bettone's conclusion that the hardness of an element is inversely proportional to its specific volume, it is shown that hardness may be represented in terms of the specific gravity, and the expression $6{\cdot}6(m + \sqrt{v})$, thus—

$$\text{Hardness} = \frac{1}{\text{spec. vol.}} = \frac{\text{sp. gr.}}{\text{at. wt.}} = \frac{\text{sp. gr.}}{6{\cdot}6(m + \sqrt{v})}.$$

But Carnelley's energies were not alone given to the investigation of questions of a purely scientific interest, for, naturally, one situated as he was all his life in the midst of active industrial communities found many opportunities of applying his knowledge and training for the benefit of those around him. Notably was this the case in the valuable examinations, chemical and bacteriological, of the air of dwellings, schools, &c., in Dundee and district, in a report to the School Board, of which he was an active member. Much valuable information was brought to light by these investigations, and it would appear that one result attained was the realization by the authorities in Dundee, Aberdeen, and some other towns, of the necessity of making provision in schools for the supply of a pure aërial food for the scholars. This subject—the ventilation and heating of schools, &c.—was, we believe, one with which he was busily engaged at the time of his last illness, and it is to be hoped that the labour which he expended upon it will be continued by one of his competent collaborateurs.

Prof. Carnelley was also the author of an elaborate and most valuable compilation of certain physical constants of chemical compounds, published in two large volumes, a monument of industry and devotion to science; he was, moreover, an extensive contributor to the German-English dictionary of scientific and technical terms published by Messrs. Vieweg and Son, of Brunswick.

Of a retiring, modest, unselfish, and deeply religious nature, his earnest enthusiasm served not only to create in all a sincere regard for him, but to make him beloved by those who were privileged, whether as teachers or students, to become intimately acquainted with him. At all times an ardent student, an untiring investigator, a successful teacher, and a contributor in so great a variety of ways to the advancement of science, by his early death an already brilliant career has been deplorably cut short and a vacancy created in the ranks of scientific men in this country which must long remain unfilled.

H. E. R.
P. P. B.

NOTES.

THE well-known writer on vegetable palæontology, Prof. E. Weiss, of Berlin, died on July 5 last.

THE Swedish residents of Chicago have subscribed for a statue of Linnæus, which will shortly be erected in the Lincoln Park in that city.

DR. A. MÖLLER, of Berlin, has established, at Blumenau in the State of S. Catharina in South Brazil, with the assistance of the Prussian Academy of Sciences, a botanical laboratory, where, during the next two years, he will pursue Brefeld's method of the artificial culture of the higher and lower filamentous Fungi. He will be glad to receive suggestions from botanists interested in the subject

THE Congress of the United States has granted the sum of 40,000 dollars, to be employed, exclusively of salaries, in the prosecution of botanical work by the Division of Botany of the Department of Agriculture. The Section of Vegetable Pathology has now been made a distinct division, and is at present especially concerned in investigating the grape-vine disease which is spreading rapidly in California.

THERE has recently been added to the marine collection at the Brighton Aquarium a specimen of the manatee, or "sea cow." The specimen has been imported from Trinidad, and was brought from Liverpool by Mr. Wells, the marine superintendent, under whose careful supervision it was safely transferred to its new home in the Brighton Aquarium. The tank in which it has been placed has been specially fitted with heating apparatus, it being necessary to keep the temperature to between 70° and 80°. The manatee is 4 feet 6 inches in length, and feeds principally upon lettuce, of which it consumes large quantities.

THE Lords of the Committee of Council on Education have just sanctioned under Clause 8 of the Technical Instruction Act, 1889, a resolution passed on August 12, 1890, by the Council of the city of Worcester. This resolution consisted in making grants, under the powers conferred upon them by the Act, to certain institutions in Worcester for the promotion of technical instruction, and it was the opinion of the Council that such a form of instruction is required by the circumstances of the district. The instruction is to be given in the following subjects, which are not included in the branches already recognized by the Science and Art Department: French, German, typewriting, shorthand, bookkeeping, commercial geography, commercial arithmetic, and cookery.

THE *Photographic News* contains an account of the eleventh annual Convention of the Photographers' Association of America, which proved a great success. The chief part of the programme was the unveiling of the monument to Daguerre at the city of Washington. The work was after the design of Scott Hartley, and is stated to be of a beautiful unique design, and worthy of the admiration of every photographer in America. The sessions, owing to the kindness of the United States officials, were held in the National Museum, and under the very able management of the executive officers an excellent programme was provided and carried out successfully. There was an unusually large number of papers presented, and the discussions were entered into by the members in the most hearty and satisfactory manner. Among other articles are those by Dr. H. W. Vogel on photography in Germany, and by Colonel J. Waterhouse on the reversal of the negative photographic image by thio-carbamides.

THE last two numbers of *Cosmos* contain some very interesting information on various topics. Some new discoveries have been made at Pompeii, near the Stabiana Gate, and a description is given of them. Three bodies were found, two being those of men and the third that of a woman. Not far from the resting place of these bodies was found the trunk of a tree, 3 metres in height, and measuring 40 centimetres in diameter. This tree, together with its fruits that were found with it, have been examined by the Professor of Botany, M. Pasquale, who finds in it a variety of *Laurus nobilis*. By means of the fruits, since they come to maturity in the autumn, he concludes that the eruption did not take place in August but in November.

THE current number of *La Nature* contains an interesting account of the ceremony of unveiling the new statue of Gay-Lussac at Limoges. In the name of the Academy of Sciences, M. P. P. Dehérain gave a long discourse on the life and works of this great man, extracts from which are given. Prince Roland Bonaparte gives a description of the race of Somalis, some of which are at present in the Acclimatization Gardens of Paris, and which form a most curious ethnographical exhibition. The article is written from observations of the author and from other sources, and deals with the country, food, habits, dress, &c., of these people who inhabit that country, "si affreux et si désolé."

IT was observed a short time ago by Dr. Kremser, that the curve of mortality in North Germany lagged about two months behind that of the variability of temperature. An inquiry into this matter in the case of Budapesth has been lately made by Dr. Hegyfoky, taking the nine years 1873–81. Comparing the months, he failed to make out a certain connection. But taking into account other meteorological elements besides temperature, and reckoning by seasons, he found the variability of weather in the different seasons to give the following order from maximum to minimum: winter, spring, autumn, summer. As regards mortality, the order was: spring, summer, winter, autumn. Thus it appears there is a displacement of three months. If a connection of the kind referred to really exists between weather and mortality, the effect, mortality, must appear somewhat later than the cause, variation of weather.

THE *National Review* for September contains an article on the progress of weather study, by H. Harries. The subject dealt with refers chiefly to the wind, and the author traces the history of the development of the law of storms and of the practical application to weather prediction. He points to the useful work of the Meteorological Department under Admiral FitzRoy in collecting synchronous observations of the *Royal Charter* storm of October 1859. The charts then published, although too limited in their area, threw much light on the movements of the atmosphere and formed a most important step in the right direction. The later investigations of the Meteorological Council of the United States Office, and of the *Deutsche Seewarte*, &c., have contributed greatly to increase our knowledge, and to improve the accuracy of weather forecasts and it is by such synchronous discussions, and by taking advantage of the reports from rapid steam vessels, that we must hope for an extension of our knowledge in the future.

MR. E. NEVILL, the Government Chemist at Natal, in his last report to the Colonial Secretary, notes that valuable deposits of argentiferous galeno of copper and of bismuth exist in the colony, and of such rich nature that they could be profitably exported in bulk. In both Alexandra and Umvoti Counties deposits of silver-bearing lead ore have been found, containing from ten to fifteen pounds worth of silver per ton of lead ore. Saltpetre has been found so rich as to be worth more than three times as much as the best Peruvian deposits. Plumbago, asbestos, and the mineral phosphates appear to be of inferior quality. Several calcareous formations have been examined, which are likely, under proper treatment, to yield good hydraulic cement.

SOME chemical reactions can be started or accelerated by sunlight, and an increased effect is to be expected where the rays are concentrated by a lens or concave mirror. Herr Brühl has recently described (in the *Berichte*) experiments made in this way, in production of zinc ethyl from zinc and ethyl iodide (a reaction difficult to start). The retort, containing zinc-filings and several hundred grammes of ethyl iodide, was placed at the focus of a concave mirror, about a foot in diameter, receiving the sun's rays. The reaction soon began, and grew so vigorous that cooling was necessary. In a quarter of an hour all the ethyl iodide was consumed, and through the subsequent distillation in an oil-bath, a good yield of zinc ethyl was had. This radiation process, it is suggested, might be variously useful in actions on halogen-compounds, which tend to be disaggregated by sunlight. A lens, owing to the athermanous property of glass, would be less powerful.

MR. A. MCADIE, Fellow of Clark University, U.S., has forwarded us his prize essay on tornadoes, reprinted from the *American Meteorological Journal* for August. After a discussion of the state of our knowledge of storms of this character, the possibility and practicability of predicting them is considered. It is suggested that, since the barometric movement is too sluggish and the thermometric indications too much masked to be serviceable, the electrometer might be better adapted to give notice and warning of the proximity of violent whirlings in the air and detect those which would otherwise pass unheeded. A careful study of cloud movement is also suggested, as a method promising much in the way of obtaining knowledge bearing on the occurrence of tornadoes.

THE Report of Dr. Eitel, Inspector of Schools in Hong Kong, for the past year, contains some interesting details. The total number of educational institutions of all descriptions, known to have been at work in the colony of Hong Kong during the year 1889, amounts to 211 schools, with a grand total of 9681 scholars under instruction. More than three-fourths of the whole number of scholars, viz. 7659, attended schools (106 in number) subject to Government supervision, and either established or aided by the Government. The remainder, with 2022 scholars, are private institutions, entirely independent of Government supervision and receiving no aid from public funds. The total number of schools subject to direct supervision and annual examination by the Inspector of Schools amounted, in 1889, to 104, as compared with 50 in 1879, and 19 in 1869. The total number of scholars enrolled in this same class of schools during 1889 amounted to 7107, as compared with 3460 in 1879, and 942 in 1869. In other words, there has been an increase of 31 schools and 2518 scholars during the ten years from 1869 to 1879, and an increase of 54 schools and 3647 scholars during the ten years from 1879 to 1889. It would seem, therefore, that the decennial increase of schools and scholars during the last twenty years has shown a tendency to keep up with the progressive increase of population. Comparing the statistics of individual years, the number of schools under supervision and examination by the Inspector of Schools rose from 94 in 1887 and 97 in 1888 to 104 in 1889, whilst the number of scholars under instruction in these same schools rose from 5974 in 1887 and 6258 in 1888 to 7107 in 1889. There is, therefore, a steady annual increase during the last three years, progressing from an increase of 284 scholars in 1888 to an increase of 849 in 1889. The expenses incurred by the Government during the year 1889, on account of education in general, amounted, exclusive of the cost of new school buildings, to a total of $53,901.

IN *Science* reference is made to a question which may interest many of our readers, "Should beer be drunk out of a glass?" Dr. Schultze claims to have established, by a very extended series of experiments, that beer, by as little as five minutes' standing in any glass, even when cold and in the dark, will be materially affected both in taste and odour. By making trial tests on some one hundred persons he sustains his claims. The change is due, as he thinks, to the slight solubility of the glass substance in the beer. Lead is used in the manufacture of glass, making it more easy to manipulate, and from experiments with glass obtained from the leading sources of supply, he determined that one cubic centimetre of beer, by five minutes' standing in glass, dissolved 6–26 ten-millionths of a milligram of the glass substance containg 0–48 thousand-millionths of a milligram of lead oxide. It is this small quantity of glass substance that affects the taste of the beer, and if it contains lead, renders it objectionable for sanitary reasons. By further experiments with vessels of different substances, he comes to the conclusion that gold-lined silver mugs are the best, and he ranks covered salt-glazed stone mugs as good.

THE United States Consul at Hanover, in a recent report refers to afforestation in that State, where, he says, there were formerly rich tracts of forests. These, in consequence of wars, were reduced to desolate wastes, and remained so until the first decades of the present century—particularly those districts between Hamburg and Hanover which are known by the name of Luneburger Haide. Another reason for the devastation was mismanagement, such as division of common forests, by which they were dispersed and fell into the hands of people with small means, and thus were doomed to neglect and destruction. The celebrated Burkhardt was appointed Director of the Forest Department in 1850, and under him part of the Luneburger Haide, as well as other tracts growing more and more desert by the encroachments of sand, have been wooded with great pains and trouble. To prevent the increase of sandy deserts those tracts were at first planted with fir-trees. After a number of years these were cleared, and beech and other trees substituted. How much the forests have been enlarged in this manner will appear by the fact that the wooded surface amounted in the year 1850 to 1,217,625 acres, and in 1885 to 1,551,900 acres. The Government granted large sums for the purchase of land unfit for cultivation to be turned into forest tracts, and is now intent on uniting again those formerly scattered wooded parts into one single tract. In the same way the Klosterkammer (Administration of cloister funds) purchase extensive stretches of soil. Municipalities, communities, and even private individuals who are inclined to establish forests and manage them rationally, will receive loans at 2 per cent. from the Provincial Government, to be reimbursed yearly by small instalments; single subsidies also are granted for converting large wastes into forest grounds. The Government employed vagabonds, tramps, and prisoners not of a dangerous character, for forest culture. In this manner about 9000 acres were planted with trees by those troublesome classes within the years 1876 to 1888. Moreover, communities as well as private individuals have turned about 14,000 acres into forest grounds within the same period by means of subsidies afforded by the Provincial Government, and various towns have laboured to preserve and plant forests in their vicinity for purposes of health, recreation, and incidentally of profit also.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♂) from India, presented by Mr. A. S. Keys; a Brazilian Tree-Porcupine (*Sphingurus prehensilis*) from Trinidad, presented by Mr. J. N. Kilner; two Vulpine Phalangers (*Phalangista vulpina* ♂ ♀) from Australia, presented by Mr. J. G. Mackie; two Pucheran's Guinea Fowls (*Numida pucherani*) from East Africa, presented by Mr. Keith Anstruther; a Silver Pheasant (*Euplocamus nycthemerus* ♀) from China, presented by Mr. E. W. H. Blagg; two Wheatears (*Saxicola œnanthe*), a Stonechat (*Pratincola rubicola*), a Whitethroat (*Sylvia cinerea*), British, presented by Mr. J. Young, F.Z.S.; an Owen's Apteryx (*Apteryx oweni*) from New Zealand, presented by Capt. E. A. Findlay, R.N.R., R.M.S. *Ruapehu*; a Blue and Yellow Macaw (*Ara ararauna*) from South America, presented by Mr. Luxmore Marshall; a Blue-eyed Cockatoo (*Cacatua ophthalmica*) from New Britain, presented by Mrs. R. E. Anson; a Guillemot (*Lomvia troile*), British, presented by Mrs. Forbes; two Common Gulls (*Larus canus*), a Black-headed Gull (*Larus ridibundus*), British, presented by Mr. A. C. Howard; a Lion (*Felis leo* ♂) from Sokoto, West Africa, deposited; a Common Bee-eater (*Merops apiaster*), European, a Green-headed Tanager (*Calliste tricolor*) from Brazil, purchased; three Garden Dormice (*Myoxus quercinus*) from Vosges, France, received in exchange; two Viscachas (*Lagostomus trichodactylus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Remarks.

(1) According to the observations of Huggin and D'Arrest, this nebula has a continuous spectrum, but further observations for "irregularities" or bright flutings should be made. The nebula is described as "Bright; pretty large; pretty much elongated in the direction 160°; suddenly much brighter in the middle."

(2) Dunér compares the spectrum of this star of Group II. with that of α Herculis, and states that "it is one of the finest in the northern sky." The bands 2–9, including 6, are very wide and dark, and the spectrum is one which may be advantageously studied. Light-curves of spectra of this type are valuable, as they show the relative extent of carbon radiation, and therefore serve as a cross check in the classification which is made on other grounds.

(3) The spectrum of this star is one of Group II., in which bands 2, 3, and 7 are dark but not very wide, and bands 4, 5, and 8 are feeble and narrow. Dunér thinks it almost intermediate between Group II. and Group III., but in this he is probably mistaken, as the description agrees almost exactly with that of 75 Cygni (see p. 511), which turns out to belong to an early and not a late species of the group. In that case the bright carbon flutings are predominant, and it will probably be found that this applies also to the star in question. Here, again, a light-curve of the spectrum compared with that of a star like (2) should emphasize this point.

(4) This star has a spectrum which is almost Group IV., the hydrogen lines being considerably broad, but, at the same time, *b* and D are seen without much difficulty. Its proper place on the temperature curve is therefore the last stage of Group III. It may be remarked that with the same thickness of F in a star of Group V., the metallic lines would not be so prominent. One need only compare Aldebaran and Capella to see this difference in the intensities of the metallic lines in Groups III. and V.

(5) A star of Group IV.

(6) In the spectrum of this star of Group VI. no secondary bands were seen with certainty by Dunér, and although the green and yellow zones are very bright, the blue light is very feeble. It seems as if in some of these stars there is more continuous absorption than in others, and comparative light-curves of the spectra of stars of the group might throw light upon this point. This again would probably enable us to determine the relative temperatures of the different stars. The intensity of the blue zone certainly does not depend altogether upon magnitude.

(7) The approaching maximum of this variable (October 4), will offer another opportunity of determining the character of its spectrum. It is much to be regretted that so many variables have as yet unknown spectra, and the sooner they are observed the better. T Herculis has a period of about 165 days, and ranges from 6·9–8·3 at maximum to 11·4–12·7 at minimum (Gore).

A. FOWLER.

SOLAR ACTIVITY FROM JANUARY TO JUNE 1890.—Prof. Tacchini has just presented to the Paris Academy of Sciences a note on the distribution in latitude of solar phenomena observed by him during the first half of this year (*Comptes rendus*, September 15). Hydrogen prominences have been more frequent in the southern hemisphere than in the northern, and reached a maximum of frequency in the zone included between the latitudes 40°–50°. This was also the case in 1889 (*Comptes rendus*, May 5, 1890). During the second quarter of this year prominences have been observed very near to the poles, which indicates that solar activity is on the increase. Faculæ show maxima of occurrence at the same distance from the equator in both hemispheres, viz. 20°–30°. The maximum frequency in the northern hemisphere is more marked, however, than in the southern. The distribution of groups of spots is the same as that of faculæ, hence Prof. Tacchini concludes that we have reached a period of change in the distribution in latitude of solar phenomena; for whilst prominences have maintained a predominance in the southern hemisphere, faculæ and spots have been more frequent in the northern. The absolute number of groups of spots during the second quarter of this year was greater than that of the first quarter, thus indicating that the minimum period has definitely passed.

THE TELLURIC SPECTRUM.—In the current number of *L'Astronomie* M. Janssen gives a short account of his work in Algeria on the telluric spectrum. The object of the expedition was to photograph the solar spectrum on isochromatic plates when the sun was respectively on the meridian and horizon. By the use of such plates, having maxima of sensibility at the less refrangible end of the spectrum, the increase in intensity of the most important telluric lines, which accompanied a decrease in the sun's altitude, may be strikingly demonstrated. The observations were made from a small fort near Biskra, situated on the edge of the Sahara, and having an uninterrupted view towards the south. The solar spectrum was obtained by means of a Rowland's grating, and many photographs were taken during the three months of observation. Their discussion is not yet completed, but M. Janssen notes that without the purity of the sky at the place of observation and the continuance of fine weather it would have been impossible to obtain any useful results. An excursion was made to Tuggurt in order to study the solar spectrum from one of the driest places on our globe. Some photographic observations of mirages were also made at the same time, and are said to throw much light on the nature of the conditions necessary for the production of these singular phenomena.

THE PERSEID METEORS.—In *Comptes rendus* for September 15, Prof. Denza gives an account of the observations made in Italy from August 9 to 11 under the direction of the Italian Association for the Observation of Meteors. From the results obtained at the thirty stations it is concluded:—

(1) The number of luminous meteors, especially on August 11 and 12, was greater than in preceding years, and has relatively attained a maximum. This appears to prove that the earth has cut through a condensation in the meteoritic ring.

(2) The meteoritic shower, which formerly began on August 10, appears to have suffered a retardation, and now begins on August 11.

(3) The following are the numbers of meteors observed at some of the stations: Vatican Observatory, 1971; Florence, 1749; Aprica, 1740; Gaeta, 1305; San Martino in Pensili, 1276; Moncalieri, 1036.

(4) The radiant of the principal shower was found to have the same position between Perseus and Cassiopeia as has previously been noted.

(5) Other radiants were also observed, and notably in Ursa Major and Ursa Minor, Cygnus and Andromeda.

(6) Most of the meteors seen had the yellow colour characteristic of this swarm.

(7) The shower was a remarkable one this year, not only because of the great number of meteors, but also because of their large size.

NATAL OBSERVATORY.—From the annual report of the Government Astronomer of this Observatory for 1889 it appears that the principal work in progress is a comparison of the declinations deduced from observations made at Observatories in the northern and southern hemispheres by a comparison by Talco's method of the zenith distances of northern stars and circumpolars both above and below the pole. Some important results have also been obtained from an investigation into the present theory of lunar motion. The meteorological observations made during 1889 have been tabulated, and will be found useful.

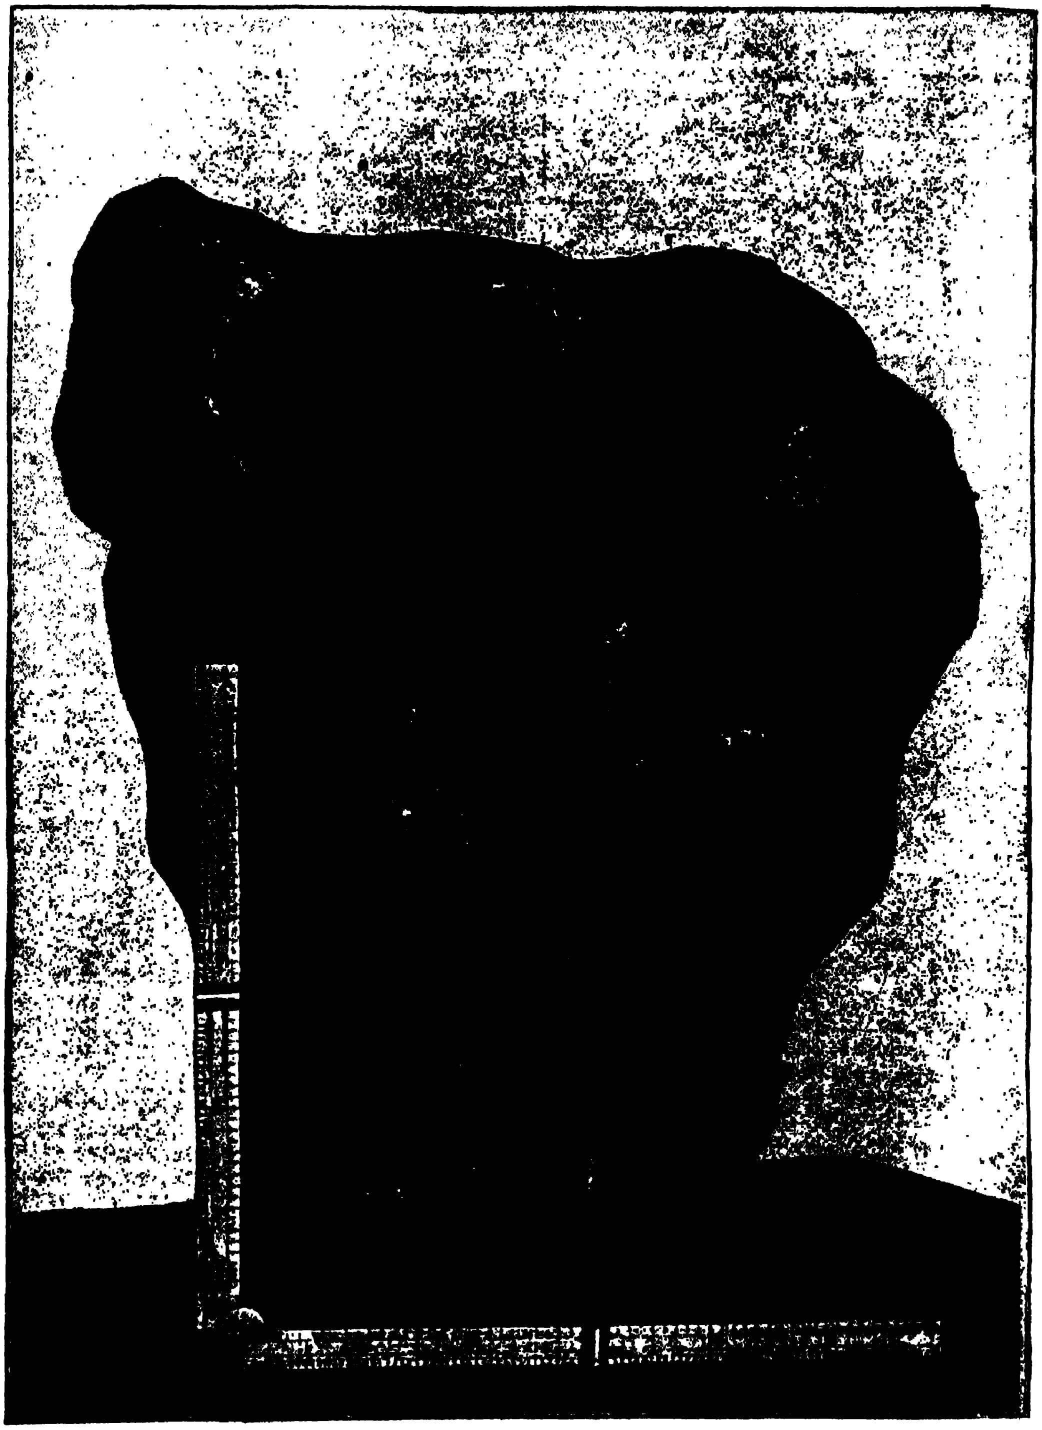
THE NARRABURRA METEOR.

THE Narraburra meteor was found in the year 1854, by Mr. O'Brien, in lat. 34° 10′ S., long. 147° 43′ E., which is a point on the Narraburra Creek about 12 miles east of Temora. When

found, it was on a hard and stony surface, but I have been unable to obtain any other particulars, as the finder has long since passed away to the majority.

Mr. O'Brien gave the meteor to Mr. Patrick Harrold, of Mount Hope, near Cootamundra, and it has been in his keeping ever since; until, on March 30, 1890, he was induced by Mr. William R. Eury, Inspector under the State Children's Relief Branch, to send it to me. Mr. Eury, as soon as he saw the meteor, pointed out to Mr. Harrold the great scientific interest attaching to it, and that undoubtedly the proper place for it was in the Observatory, where a collection of these so-called shooting-stars is being made, and upon this, Mr. Harrold sent it to me. I am very much indebted to both of these gentlemen for enriching the Observatory collection by this most interesting specimen of a metallic meteor. Our museum for meteors now contains six.

In appearance this meteor is like rusty iron, and it has a very irregular outline, which seems to have resulted from the oxidation or solution of rounded masses, which had solidified with the iron, and upon removal formed cavities. In size it measures 11 inches × 7½ inches. Two of these are so placed that they look like the orbits in an ox's skull, a suggestion borne out by



the general outline, which is not unlike the bone in question. In one place a hole nearly 1 inch in diameter and 1½ inch deep, has been made straight into the solid iron, and there seems to be little doubt that, when the iron originally cooled down from its gaseous state, it did so in the presence of these rounded and symmetrical masses, which impressed their form on the plastic iron as it solidified. These, as I have already suggested, have no doubt been removed since they reached the earth's atmosphere.

A meteor which fell in New England in November last was seen to have a spiral motion, emitting steam or smoke in jets. Looking at the holes in this meteor, one can see at once that if, when it reached the atmosphere, they were charged with some substance that would burn freely in the oxygen of the air, this solid mass of iron would have twisted about under the influence of the many gas-jets from the burning masses in its sides.

I find its specific gravity is 7·57 and its weight is 71 pounds (70 pounds 14 ounces). Meteoric iron is, I think, never quite pure, and masses of it vary very considerably in specific gravity. Taking five at random which fell in different parts of the earth, it varies in them from 7·38 to 7·82, and the mean happens to be 7·62, almost exactly the same as the one before us.

This meteor has not been analyzed yet.

July 26 H. C. RUSSELL.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE thirty-ninth annual meeting of this body was held on August 20-26 at Indianapolis, which is the capital and largest city of the State of Indiana, and is the largest inland city of the United States, being a railroad centre without navigable water of any kind, and having, with its suburbs, a population of about 140,000.

Near the city is located the greatest region of natural gas in the world. The manufacturing business of this whole region has received a wonderful stimulus from the discovery of natural gas, which has caused a rapid increase in population and manufacturing within the past three years. The gas is found in the Trenton limestone at a depth of nearly a thousand feet over a large area north and east of the city, and, besides being used *in situ*, is brought to the city in pipes for use there, where it has displaced other fuel in the large factories. One of the most instructive object-lessons the Association has ever had was the excursion on Saturday through this gas belt, stopping at Noblesville (whence the supply for Indianapolis is drawn), Kokomo, Marion, Muncie, and Anderson. At the latter place a remarkable exhibition was made of gas forced through the river and ignited upon the surface. President Goodale warned the citizens in an address of the necessity of economizing this resource, since it is not inexhaustible.

The sessions of the Association were held in the new Capitol, a fine building completed only two or three years ago at the cost of about 2,000,000 dollars, and decidedly the most sumptuous quarters ever offered to the Association, being also spacious enough to accommodate all the eight Sections under one roof.

A number of affiliated associations meet at or about the time of the principal one. Of these the Society for the Promotion of Agricultural Science, and the Society of American Geologists preceded the main meeting, while the Botanical, Entomological, and, this year for the first time, the Ornithological Club, met at intervals between meetings of the parent Association.

On Wednesday morning the retiring president, Prof. T. C. Mendenhall, called the Association to order, and resigned the chair to Prof. George L. Goodale, President-Elect. The morning was devoted to addresses of welcome and responses, and to the organization of the several sections. Among the speakers were Mayor Sullivan and Lieutenant-Governor Chase. An invitation was received from the Australasian Association for the Advancement of Science to attend the meeting at Christ Church, New Zealand, in January 1891, and President Goodale was deputed, and will attend as a delegate.

In the afternoon the eight Vice-Presidents read their several annual addresses before their respective Sections. These addresses were generally ably written.

Section A (Mathematics and Astronomy) was addressed by Prof. S. C. Chandler, of Harvard, on the variable stars. The number of these discernible with an ordinary field-glass is two thousand, while our largest telescopes reveal, perhaps, hundreds of thousands. The cycle of change, commonly called the period, ranges from less than eight hours in the wonderful variable recently found by Paul, up to two years. Between these limits is a highly significant deviation from uniformity of distribution. At least five-sixths of the variables are reddish, and the redness of the variable stars is, in general, a function of the length of their period of light variation. The redder the tint, the longer the period. An examination of fluctuations in brightness, or light curves, enables us to distinguish a number of types, of which the most remarkable is that of Algol. The cause of variability is still problematic, except for the ten stars of the Algol type, which seem to be explained by the theory of an occulting satellite, somewhat modified however. For the other types we may perhaps seek an explanation in certain consequences of rotation of the stars upon their axes, or by introducing modifying suppositions of unequally illuminated surfaces, irregular forms, tidal action upon light-absorbing atmospheres, spontaneous and intermittent explosions, meteor swarms, and the like.

Section B (Physics) was addressed by Prof. Cleveland, Abbé of Washington, colloquially designated throughout the United States "Old Probs," for the reason that he is in charge of the weather bureau, and makes up the daily weather report, with indications, formerly called probabilities. His theme was terrestrial physics. There are two kinds of physics—molecular and terrestrial. The latter he names, following the German nomenclature, geo-physics. It relates to the earth as a whole, including all phenomena relating to earthquakes, volcanoes, gravitation, and the variations in its intensity on land and sea, mountain, plain, and valley, magnetism of the earth, tidal motion and tidal stress of the earth's crust as well as of the ocean, and in general the study of the entire interior of the earth, of the earth's crust, both land and water, meteorology, auroras, &c. He deplores the lack of laboratories for such researches, and deems a good geo-physical laboratory a great desideratum. He urges that some such institution should be founded and endowed, rather than to continue the founding of laboratories for research in chemistry or molecular physics of which so many are already in existence, or the establishment and endowment of universities to teach only what is already known.

The address of Prof. R. B. Warder, of Washington, to Section C (Chemistry), on geometrical isomerism, was decidedly the most abstruse of the series, but to one able to follow him, it was of unusual interest, giving the latest results of study into the subject of the relative positions of atoms in a molecule, including a careful study of the right-handed and left-handed carbon molecules. Most of this material is very recent, the prominent workers, such as Wislicenus and Wunderlich, having made more progress within two or three years than in any previous period. Besides the speculative interest of these studies they have a very important practical application in the physiological and pathological action of isomers, many of which, while identical in chemical constitution, affect living organisms very differently, whether administered as food or as medicine.

Prof. James E. Denton, of Hoboken, addressed Section D (Mechanical Science and Engineering) on mechanical tests of lubricants. Experiments to determine the co-efficient of friction between lubricated rubbing surfaces have been prosecuted for two hundred years, and have resulted in the existence of many forms of satisfactory apparatus for such measurement, which are now known as oil-testing machines. The overheating of bearings is due, however, to accidental abrasion of rubbing surfaces, which generates an intense heat at some points, and tends to vaporize some oils more than others. Oil-testing machines are inadequate to reveal these differences, and moreover the supply of oil is artificially abundant, instead of feeding through practical forms of oil-cups. It is concluded, therefore, that each oil must be tested with a series of conditions of the rubbing surfaces, and practical feeding devices which involve opportunities for abrasion and overheating. Explanation was given of the paradoxical fact that overheating is often remedied by supplying sand or emery to bearings. The sand grains make grooves around the wearing parts, and as a result the oil is uniformly distributed, and the hot-box cools down to the limit of safety.

Prof. John C. Branner, State Geologist of Arkansas, addressed Section E (Geology and Geography) on relations of the state and the national geological surveys to each other. He thus recapitulates the benefits to be derived from voluntary cordial co-operation between all geologists and all geological organizations in this country.

"(1) Geologic research being under the nominal direction of the leading investigators would be so conducted as to be of the greatest utility to the greatest number.

"(2) When a piece of work was done by one it would be done for all, and duplication by state surveys and by individuals, and the consequent waste of energy, time, and money would cease.

"(3) The functions and fields of official organizations being better defined, state and national surveys and individuals could so direct their efforts as to serve the purposes of others without neglecting their own immediate aims, and without infringing upon each other's ground.

"(4) National and state surveys would be strengthened, and local organizations and individual effort encouraged.

"(5) It would give us a better geologic literature, better instruction, better geologists, and more thorough specialists.

"(6) And finally, we trust it would put a stop to those oracles of science who are so ready to prophesy in its name."

Dr. Charles S. Minot, of Boston, addressed Section F (Biology) on certain phenomena of growing old. The loss of vital power commences from birth; the older an organism is the more time it takes to produce a given change, and this indicates a progressive loss of vitality. Anatomical peculiarities can be found correlated with this progressive loss of vitality. Considering in detail the various tissues of the body in the order of

their development, in each of the principal tissues and organs of inner, middle and outer layer of the body, the cells composing them show the same peculiarity, namely, that in their young condition they contain only a small amount of protoplasm, and in the adult condition a very much larger amount, so that the proportion of protoplasm to nucleus increases with the age of the organism. The conclusion is that development of protoplasm is associated with loss of vitality. So that instead of speaking of protoplasm as the physical basis of life, we might term it the physical basis of advancing decrepitude, or in other words, the physical basis of death. The reverse development is seen in generation, where the first process which the fecundated ovum undergoes is segmentation into numerous nuclei, with attendant decrease in the proportion of protoplasm to nucleus, and precisely the same phenomenon is noted in animals which multiply by fissure, the tissues at the point of fissure becoming greatly segmented.

Dr. Frank Baker, of Washington, addressed Section H (Anthropology) on the ascent of man, in which he traced with much detail the modifications which the body has undergone in ages of development, the more striking modifications being those connected with the limbs, the change from quadrupedal to erect posture and the segmentation of the body, and indications of change being left as vestigial organs. The erect position is gradually acquired, and the difficulty that an infant experiences in learning to walk erect is strong evidence that it is an accomplishment acquired by the race late in its history. The human body gives evidence of a previous semi-erect position. The special changes of structure which secure the erect position are less marked in children and in the lower races. In the course of evolution of these changes, there is a period of struggle before the body becomes thoroughly adapted to them. Such struggle is still going on, the adaptation being far from complete. Hence the liability of man to certain deformities and diseases, to which quadrupeds are not so much disposed. It is in just this line that is to be found the explanation of the greater difficulty and dangers of parturition in the human family, and of the fact that woman in her entire organism has suffered more than man in the upward struggle. The increased influence of gravity also explains the greater tendency to certain disturbances of the circulatory organs. Study of the bony skeleton gives, in man, evidence of his relationship, in origin to the lower animals, as in the persistence of relics of ribs, and in unmistakable signs that the skull is composed of segmented pieces like the vertebræ. The evidence of such relationship has come, and is coming from all sides, from the study of comparative brain weight and structure, of the facial angle, the face bones and teeth, with their resulting changes in expression from brute or brutal man to the highest types, in which the brain shows its rulership in the countenance

Prof. J. R. Dodge, of Washington, addressed Section I (Economic Science and Statistics) on the standard of living in America. Prof. Dodge is chief of the agricultural bureau of statistics of the United States, and his report of the condition of growing crops on the 10th of every month is always eagerly awaited, and has a great effect on market prices of agricultural produce of all kinds. The American standard of living is the highest known. To maintain it, wages are and should remain high. Production is not thereby diminished because of the brain power of the American people and our utilization of labour-saving machinery, so that in many articles exportation increases enormously despite high wages. Our woods are tougher than those of Europe, and we would not accept European tools if given to us.

His most important conclusions are: The question arises, Shall the present standard of living be maintained? It is a point upon which hangs "the future education, enterprise, independence, and prosperity of the people" of the United States. It depends on the industry of the producing classes, and wisdom in the distribution of their labour for a production that shall meet their wants. If idleness shall be encouraged, production limited, importation enlarged, and dependence on foreign countries fostered, wages will be reduced, and the ability to purchase as well as the volume of production will decline. If the advice of public and private teachers of repressive economy to buy everything abroad, and sit down in the enjoyment of the luxury of idleness at home, shall become the law of the land, short rations will follow, and high prices will only be abated by the inability of our people to purchase for consumption.

Unless the largest variety of production shall be encouraged, and the highest skill shall be stimulated in the endeavour to meet all the wants of our people by the results of our own labour, it will be impossible for us to have a surplus for export. It is a matter of time, of determined effort, of high endeavour to render high wages consistent with large exportations of surplus, but the future will accomplish it, if the present scale of living and rate of wages of the American people shall be maintained.

Wednesday evening was taken up with the address of the retiring president, Prof. T. C. Mendenhall, chief of the United States Geodetic and Coast Survey, who spoke on the relation between men of science and the community. He began by calling attention to the fact that this association is the outgrowth of the Association of American Geologists and Naturalists organized just fifty years ago. He spoke of the duty assigned the retiring president to present an address as giving an opportunity to dismiss the relationship between members of the Association and the general public whose interest is often born of curiosity rather than intelligent appreciation. The meetings of this Association have been the means of disseminating proper methods of investigation and study throughout the land. He considered various elements of weakness in scientific men such as assumption of superior knowledge in lines of investigation outside of their own specialties, lack of a proper amount of utilitarianism, as well as lack of interest in political affairs, contrasting this spirit with the distinguished service rendered to mankind by such scientific men as Newton, Watt, and Franklin. The ideal of duty which ought to be present in the mind of every man of science may well be higher than that growing out of mere selfish pleasure in the acquisition and possession of knowledge.

The remaining days of the session—Thursday, Friday, Monday and Tuesday—were devoted to general business and the reading of papers in the sections. On Friday evening Dr. H. C. Hovey lectured on Mammoth, Marengo, and Wyandotte caves, and on Monday evening Prof. C. Leo Mees lectured on electricity.

The general business included an appropriation of 250 dollars to Prof. E. W. Morley for the further prosecution of his researches in the velocity of light in a magnetic field; resolution of thanks to two Brazilian gentlemen for removing to the museum at Rio the largest meteor ever found, weighing five tons; resolution requesting Congress to provide fire-proof quarters for the botanical collection at Washington, and another urging protection of the forests; resolution favouring the use of the metric system at Custom houses in the United States.

It was decided to hold the next annual meeting at Washington, and invitations were sent to other governments on the American continent to send delegates, thus giving to this meeting, which is the only one held at Washington in recent times, an international character.

The Association adopted the report of the committee of anatomical nomenclature, which recommends the following changes, with special reference to the brain: "That the adjectives dorsal and ventral be employed in place of posterior and anterior, as commonly used in human anatomy; and, in place of upper and lower as sometimes used in comparative anatomy; that the cornua of the spinal cord and spinal nerve roots be designated dorsal and ventral rather than posterior and anterior; that the costiferous vertebræ be called thoracic rather than dorsal; that the hippocampus minor be called calcar; that the hippocampus major be called hippocampus; the pons variolii, pons; the insula Reilii, insula; pia mater, pia; dura mater, dura."

Two hundred and fifty-nine papers were read, of which the largest number, fifty-one, were in the section of physics, and the next largest, forty-eight, in biology. It is difficult to attempt a selection without doing injustice, but a few of the papers deserve mention, while perhaps others, equally meritorious, may be overlooked. Prof. Cleveland Abbé read papers by himself on kinematic methods of determining the altitudes and motion of the clouds, and, by Frank N. Bigelow, on further study of the solar corona, and on terrestrial magnetism. The corona is deemed to consist of matter streaming out from the sun in zones about 32° distant from the poles, and falling back into the region of sun-spots, which are, probably, thus caused. It is regarded as similar to the earth's aurora, though of denser matter.

Prof. T. C. Mendenhall, in his paper on the use of the magnetograph as a seismoscope, showed that earthquakes are caused by the tidal stress of sun and moon upon the earth's

crust, and are accompanied by magnetic currents which serve as indices of their approach.

Prof. E. W. Morley's report on the velocity of light in a magnetic field shows an increase in velocity in such a field amounting to seven parts in one thousand million. These investigations are to be continued.

Prof. Morley also read a paper on the determination of the volumetric composition of water, and one on the ratio of the density of oxygen and hydrogen. In twenty determinations the minimum value of combination in water was 2·0005, the maximum was 2·00047, mean 2·00023, with a probable error of one part in 30,000. The value two to one, which every schoolboy learned is the ratio of hydrogen and oxygen in water, must be increased about one nine-thousandth. In two determinations of density, Morley reaches the same result as Rayleigh, viz. 15,884, giving 15,882 as the atomic weight of oxygen. Prof. W. A. Noyes read a paper on the atomic weight of oxygen, giving the results of four series of six determinations with apparatus devised by himself. The value found is 15,896, or about seven one-hundredths less than the usually accepted one.

The series of papers on distribution of North American plants, prepared on topics assigned last year, was pronounced by the presiding officer the most remarkable ever presented to the biological section. They were on the distribution of the North American umbelliferæ, by John M. Coulter; the distribution of hepaticæ of North America, by Lucien M. Underwood; geographical distribution of North American grasses, by W. J. Beal; geographical distribution of North American cornaceæ, by John M. Coulter; and the general distribution of North American plants, by N. L. Bulton. The following assignments were made for next year:—The absorption of gases, J. C. Arthur; the aëration of aquatic plants, W. P. Wilson; the absorption of fluids, L. H. Pammel; the movement of fluids in plants, W. J. Beal; transpiration, C. E. Bessey.

The exhibition of apparatus included some delicate seismoscopes and seismometers. Prof. Mendenhall exhibited some of the metric standards recently distributed by the International Congress, in the manufacture of which to distribute to all nations, two-thirds of all the iridium in the world was used. Prof. W. A. Rogers exhibited a precision screw 8 feet long, with a variation of only 1/8000 of an inch in its entire length.

Officers elected for the Washington meeting were: President, Albert B. Prescott, of Ann Arbor, Mich.; Vice-presidents, Section A, E. W. Hyde, of Cincinnati, O.; Section B, F. E. Nipher, St. Louis, Mo.; Section C, R. C. Kedzie, Agricultural College, Mich.; Section D, Thomas Gray, Oene Haute, Ind.; Section E, J. J. Stevenson, New York; Section F, J. M. Coulter, Crawfordeville, Ind.; Section H, Joseph Jastrow, Madison, Wis.; Section I, Edmund J. James, Philadelphia, Pa.; Permanent Secretary, F. W. Putnam, Cambridge, Mass. (holds over); General Secretary, Harvey W. Wiley, Washington, D.C.; Secretary of the Council, Amos W. Butler, Brookville, Ind.; Treasurer, William Lilly, Manch Chunk. Secretaries of the sections: Section A, E. D. Preston, Washington, D.C.; Section B, A. McFarlane, Austin, Texas; Section C, T. H. Norton, Cincinnati, O.; Section D, William Kent, New York; Section E, W. J. McGee, Washington, D.C.; Section F, A. J. Cook, Agricultural College, Mich.; Section H, W. H. Holmes, Washington, D.C.; Section I, B. E. Vernon, Washington, D.C.

This ticket was elected as reported from the nominating committee, except that a substitution was made in the Vice-President for Section I, which is notable as the first instance in the history of the Association in which any change was ever made in the list of nominees reported. WM. H. HALE.

CHEMISTRY AT THE BRITISH ASSOCIATION

MANY of the papers read in Section B this year were of considerable theoretical importance. Additional interest was also given to the proceedings by the presence of several distinguished foreign guests.

After the President's Address, Prof. Dunstan read the third Report of the Committee on the present methods of teaching chemistry. During the past year the Committee has been principally engaged in collecting and comparing the regulations issued by the more important of the examining bodies in the kingdom, in order to discover how far their requirements were in harmony with such a course of instruction as that suggested by the Committee in their second Report, presented at the Newcastle-on-Tyne meeting. The Committee direct special attention to the following points:—

It is of great importance that natural science should be sufficiently represented on the board which issues the regulations and is responsible for the proper conduct of the examination.

In addition to examinations, periodical inspection of the teaching seems desirable, the reports of the inspectors as well as the students' own record of work testified to by the teacher being taken into account in awarding prizes, certificates and grants, in addition to the results of an examination.

With respect to the schedules and examination papers, for the most part they do not aim at an educational training of the kind suggested in the Committee's last report, being on the other hand more suitable for those who wish to make a special and detailed study of chemistry as a science. The obvious conclusion is that the necessary reforms can only be brought about by the active co-operation of examiners and teachers.

Sir Henry Roscoe introduced a discussion on recent legislation for facilitating the teaching of science. He drew attention to the powers given by the Technical Instruction Act of 1889, to County Councils and other local authorities, and assured his hearers that the Education Department and the Science and Art Department were extremely anxious to give local authorities a free scope, and free choice of subjects. Referring to the action of the Chancellor of the Exchequer, which placed in the hands of the County Councils this year the sum of £743,000 to be devoted, whole or in part, to the purpose of technical education, he urged upon these bodies the importance of taking full advantage of this grant. In the discussion which followed hopes were expressed that the money would not go simply towards the relief of the rates. It was also remarked that for the success of these provisions it is necessary that more attention should be given to primary education.

Dr. J. H. Gladstone and G. Gladstone read a paper on the refraction and dispersion of fluorbenzene and allied compounds. Fluorine behaves quite differently to chlorine, bromine, and iodine, as it exerts scarcely any refractive action upon the light rays, and it has the property of reversing the dispersion produced by other substances.

Dr. G. H. Bailey and J. C. Cain gave a paper on a method of quantitative analysis by weighing precipitates suspended in liquids. The object of the method is to do away with the operations of filtering and washing. The specific gravity of the precipitate having been determined once for all, it is weighed together with the supernatent liquid in a specially constructed measuring flask. The specific gravity of the supernatent liquid can be readily determined, and hence the weight of the precipitate calculated. The method is found to be rapid, and to give results of sufficient accuracy for many technical purposes.

Dr. G. H. Bailey and A. A. Read gave a paper on the behaviour of different metallic oxides when exposed to high temperatures. This is a continuation of work previously published in the Journ. Chem. Soc. on oxide of copper. The following oxides were subjected to high temperatures in an oxidizing atmosphere:—SnO_2, Bi_2O_3, V_2O_5, PbO WO_3, MoO_3. The following results were obtained:—V_2O_5 was converted into V_2O_3, SnO_2 lost weight slightly, and MoO_3 lost oxygen, and was transformed into the blue oxide of molybdenum, the others were unchanged. It was suggested that some light might be thrown by the experiments on the formation of minerals in nature.

A paper was then read by Dr. G. H. Bailey on the spectrum of the haloid salts of didymium. The influence of dilution and of various reagents on the intensity of the different bands was studied. It was found that the addition of nitric acid to the solution of didymium chloride influenced some bands quite differently to others. Again the variation of the halogen element, in combination with the didymium, brought about differences in the relative positions of the bands. In addition to these, observations were also made on the effect of polarised light. Each of these different conditions influenced the bands sometimes in intensity, sometimes in position, and this in a selective manner. The connection was pointed out between these results and the experiments of Welsbach on the fractionation of didymium.

Prof. Armstrong read the fifth Report of the Committee on isomeric naphthalene derivatives. A complete set of reference compounds has now been prepared in the disubstituted series. It is found that although 13 dichlor naphthalenes have been

described only 10 exist. Of the 14 possible triderivatives 13 are known. Light has been thrown by these researches on the mode of action of reagents upon naphthalene and other hydrocarbons, and it appears that in all cases the initial action is the same, the ultimate product depending on secondary causes, *e.g.*, in the case of benzene an ortho compound is always first obtained, meta and para compounds being produced by secondary causes. The influence of structure on the colouring properties of naphthalene derivatives has also been studied in connection with these researches.

Prof. J. H. Van't Hoff read a paper on the behaviour of copper potassium chloride and its aqueous solutions at different temperatures.

This compound, which is a blue salt, splits up on heating into potassium chloride, water, and a brown double salt, according to the following equation : $CuCl_2\ 2KCl_2H_2O = CuCl_2KCl + KCl + 2H_2O$. On cooling the reverse change takes place. The brown salt can also be formed by the action of cupric chloride on the blue salt thus : $CuCl_2\ 2KCl\ 2H_2O + CuCl_2\ 2H_2O = 2CuCl_2KCl + 4H_2O$. The changes of volume attending these transformations have been studied, also the solubility of the various constituents of the system at different temperatures, and the vapour pressure of their solutions, and interesting relations are shown to exist between the values obtained in each case.

Dr. Richardson read the Report of the Committee for the investigation of the action of light on the hydracids of the halogens in presence of oxygen.

It has been found that the presence of 10 per cent. hydrochloric acid prevents all decomposition of chlorine water, even after long exposure to sunshine.

Aqueous solutions of pure bromine and iodine have been exposed to sunlight for a period of fourteen months. It was found that, in a dilute solution of bromine water (0·16 per cent. Br.), as much as 57 per cent. of the total bromine is converted into hydrogen bromide ; in a saturated solution the minimum amount of decomposition occurs, again increasing with further additions of bromine. With iodine water under an atmosphere of carbon dioxide, 8·3 per cent. of the total iodine in the solution was converted into hydrogen iodide. Under an atmosphere of air 14·2 per cent. of the total iodine was converted. Further experiments have been made on the oxidation of gaseous hydrogen bromide in sunlight. The presence of free bromine exercises a retarding influence on the decomposition.

The influence of temperature on the oxidation of hydrogen chloride and bromide has been studied. Rise of temperature appears to retard oxidation in the first case and accelerate it in the second.

Profs. Liveing and Dewar gave a paper on some experiments on the explosion of gases under high pressure. It was found that with increase of pressure the luminosity of the flame steadily increased. When hydrogen was exploded with excess of oxygen, it was found that large quantities of nitrogen peroxide were formed from the nitrogen present as impurity in the oxygen. The water formed contained 3 per cent. of nitric acid. With excess of hydrogen small quantities of ammonia were formed. It was found that, in an atmosphere of carbon dioxide, it was very difficult to maintain the oxy-hydrogen flame if the pressure exceeded two atmospheres. Experiments were also made with ethylene and cyanogen exploded with oxygen.

Prof. H. B. Dixon and J. A. Harker gave a paper on the rates of explosion of hydrogen and chlorine in the dry and wet states. They showed that there was no great difference in the rate, such as they had previously found with carbonic oxide and oxygen mixtures, thus showing that, in the case of hydrogen and chlorine, the aqueous vapour simply acts like any other inert gas, making the rate a little slower.

Dr. G. S. Turpin read a paper on the ignition of explosive gaseous mixtures. The author has commenced a thorough investigation of the conditions affecting the ignition of explosive mixtures of gases, and the present paper gives an account of the results obtained in a series of experiments on the temperatures of ignition of various mixtures of CS_2 vapour with oxygen and other gases. The method used is a modification of Mallard and Chatelier's second method, in which the gases are introduced into a heated and exhausted bulb. The existence of a discontinuity between gradual combustion and ignition proper is found to exist in some cases, while in others there is a perfect gradation from slow combination, attended by a faint glow, to instantaneous combination, attended by a bright flame. The effect of change of pressure on the ignition was examined and found to be somewhat complex.

The Report of the Committee on the properties of solutions was read by Dr. Nicol. The experiments have now been completed on the solubility of a salt in a solution of another salt, of known strength. In general a salt is less soluble in a salt solution than in pure water. An exception is the case of the solubility of KNO_3 in solution of $NaNO_3$.

A joint discussion with Section A on the nature of solution and its connection with osmotic pressure was opened by Prof. Pickering, in a paper on the present position of the hydrate theory of solution. The supporters of the hydrate theory claim that the curved figures, representing the properties of solutions of various strengths, show sudden changes of curvature at certain points, which are the same whatever be the property examined, which correspond to the composition of definite hydrates, and which, therefore, can only be explained by the presence of these hydrates in the solutions ; while the supporters of the physical theory, now identified with the supporters of the osmotic pressure theory, claim to have shown that, with weak solutions at any rate, the dissolved substance obeys all the laws which are applicable to gases, and that, therefore, its molecules must be uninfluenced by, and uncombined with, those of the solvent.

With regard to the lowering of the freezing-point of a solvent, the following questions were proposed :—

(1) Is the molecular depression (*i.e.* that produced as calculated for one molecule dissolved in 100 molecules) constant, independent of the nature of the solvent?

(2) Is it independent of the strength of the solution, so long as this strength does not exceed the limits (gas strength) above mentioned? (Boyle's law).

(3) Is it independent of the nature of the dissolved substance? (Avogadro's law).

Evidence was adduced involving a negative answer to each of these questions.

Objection was taken to the theory of dissociation into ions, on the grounds of its irreconcilability with our ideas of the relative stability of various bodies, and with the principle of conservation of energy.

A letter was afterwards read from Prof. Arrhenius in which it was shown that both the osmotic pressure and the electrical dissociation theories must be taken into account in drawing conclusions from observed numbers.

Prof. Armstrong remarked that, according to the electrical dissociation theory, hydrochloric acid and water must be regarded as entirely different substances, whereas in their chemical relations they are very nearly allied.

Prof. Fitzgerald, Prof. Ostwald, and Prof. Lodge all spoke to the effect that Ostwald's experiment, on the decomposing effect of a charged body on a salt solution, does not involve a contradiction of the principle of the conservation of energy.

P. J. Hartog and J. A. Harker described a convenient form of apparatus for determining freezing-points, and for performing reactions in the cold. Adopting a proposal of Raoult, the evaporation of a volatile liquid is used to produce low temperatures.

A paper was given by A. G. Green, C. F. Cross, and E. J. Bevan, on a method of photographic dyeing and printing. It was observed that the diazo-compound of primuline was decomposed by light, thereby losing its property of combining with phenols and amines. If a material, dyed with diazotized primuline, be exposed to light under a design, those parts which are acted upon by light will be decomposed, whilst the parts protected from the light will remain unaltered, and consequently on subsequent development with a phenol or amine, will produce colours, whilst the decomposed portions will not.

Prof. Thorpe gave a demonstration of some of the most striking properties of phosphorous oxide. He believes that the physiological effects usually ascribed to phosphorus are due in reality to this oxide.

Prof. R. Meldola read a paper on diazo-amido-compounds, a study in chemical isomerism. The paper dealt largely with heterogeneous diazo-amides, which the author believes have the general constitutional formula—

$$\begin{array}{l} X—N—N—NR'—Y \\ \quad\ \ | \quad\ \ | \\ Y—N—N—NR'—X \end{array}$$

thus being derivatives of a hypothetical tetraimine—

$$\begin{array}{l} HN—NH \\ \ \ \ | \quad\ \ | \\ HN—NH \end{array}.$$

Compounds have been prepared of all degrees of stability, from well-defined individuals to molecular compounds. The above general formula has been given for chemical reasons. A molecular weight corresponding to half that represented by the above formula is given by Raoult's method, but it is believed that dissociation takes place in solution.

C. H. Bothamley read a paper on the action of phosphorus trichloride on organic acids and on water. The equation given in the text-books, representing the action of phosphorus trichloride on organic acids, is shown to be incorrect. An equation given previously by Thorpe is confirmed, viz. :—

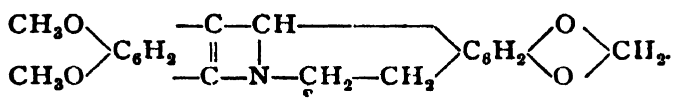
$$3CH_3COOH + 2PCl_3 = 3CH_3COCl + P_2O_3 + 3HCl.$$

The reaction, however, only takes place according to this equation in the case of acids of low molecular weight, and when the reacting substances are present in the required proportions. As the molecular weight of the acid increases the reaction tends to become more complex.

A paper was read by Prof. W. H. Perkin, Jun., on the constitution of the alkaloid berberin. On treatment with permanganate the alkaloid yields three principal oxidation products of the following empirical formulæ :—

$$C_{20}H_{17}NO_8, C_{20}H_{17}NO_7, C_{20}H_{17}NO_6.$$

From the results of the careful investigation of these, the following formula has been proposed for berberin :—



In the course of the meeting interesting discourses were given by Dr. W. H. Perkin on the development of the coal-tar colour industry since 1880, and by Prof. Hummel on fast and fugitive coal-tar colours.

GEOLOGY AT THE BRITISH ASSOCIATION.

THE short but extremely useful address of the President, A. H. Green, Professor of Geology at Oxford, formerly of Mathematics and Geology at the Yorkshire College, dealt with the educational aspect of Geology. Although he dwelt on the risk of becoming loose reasoners, which geologists continually ran, the President pointed out how by a proper training in minute and delicate experimental work, the student might be taught the necessity of exactness, and could then proceed to practical work, which would lead him into the open air, and compel him to acquire the eye and enthusiasm necessary for geological research.

Amongst the reports presented to the section was one by Prof. T. R. Jones, describing a *Saccocaris* from the Arenig, *Aristozoe* and *Estheria* from the Devonian and Carboniferous; one by Mr. G. R. Vine, giving lists of Cretaceous Polyzoa from the Neocomian, Gault, Upper Greensand, Cambridge Greensand, and Red Chalk; one from Mr. A. Bell giving the lists of fossils obtained from the "manure gravels" of Wexford, by which he is able to indicate the date of the final separation of Ireland from England; and one from Mr. Marr, giving the proposed circular letter and record sheet to be issued to the curators of public and private museums, in order to obtain a reliable register of the location of all type specimens of fossils.

Mr. Jeffs presented the report of the Photograph Committee containing a list of about 300 photographs of geological interest, and suggestions for their collection and registration; he also exhibited photographs collected during the present year, amongst which some from Yorkshire, Antrim, and Scotland were of especial value; Dr. H. Johnston-Lavis gave an elaborate report on the volcanic phenomena of Vesuvius, including a plan of the cone in April 1890, an estimate of the lava extruded between May and December, 1889, and a general record of the doings of the volcano in the year; while Mr. De Rance's report on underground water included an immense number of well sections in different parts of England.

The chief papers contributed to the section were perhaps those on local geology, some of which gave the results of many years' research. Mr. Holgate described the coals and clays of Leeds, and showed that the colour and texture of the containing rock was influenced by the nature of its fossils; thus, the more delicate plants like ferns give blue, larger plants black, and animal remains hard, black rocks. He followed with a paper on the physical properties of coals, in which he showed that coals with a dull black colour and a wide cleat were chiefly made of spores, with but little fusible ash, and were the best for use where the temperature is high; while the bright, soft coals, with close cleavage, made largely of mineral charcoal and probably of plant stems, contained much fusible ash, broke up in burning and formed slow burning, caking coals. Mr. J. R. Dakyns described the setting in of the Yoredale beds in Yorkshire, and the gradual changes which occur in them and in the lower and upper Millstone grit as the beds are traced northwards; Messrs. Cash and Lomax accentuated the identity of *Lepidophloios* and *Lepidodendron*, of which plants a magnificent series of slices was displayed in the temporary museum; Mr. J. W. Davis stated that fish remains had been found at nine horizons in the West Riding coal-field, from two of which, one above the Better bed and the other in the Adwalton Cannel of Tingley, no less than sixty species of fish and some of Labyrinthodonts had been described. Mr. Tate identified the so-called "Ingleton Granite" as a quartzose volcanic tuff, and Phillips's dyke at Ingleton as a mica-trap belonging to the minette group; Dr. Hatch also described mica-trap dykes from nine localities in West Yorkshire. Prof. Silvanus Thompson gave the results of experiments on the sources of the river Aire made by means of the fluorescent properties of uranin, and Mr. Maule Cole described a lacustrine deposit of post-glacial age near Filey.

Mr. Lamplugh dealt with the famous cliff section at Speeton, which was in capital condition for the inspection of a geological excursion on Saturday. He divided it into five zones by its belemnites, and by means of this classification was able to correlate its divisions with those of Lincolnshire. The same author gave a table of the Yorkshire boulders, from which he concluded that the North Sea ice stream drove that from the valleys of the Tees and other northern rivers southward and pressed it against the high eastern coast of Yorkshire. In a second paper he argued that the North Sea ice which formed the Basement Clay with its shelly inclusions, overtopped the Speeton cliffs and overrode Flamborough Head, passing into Bridlington Bay; the purple clays of Holderness were the equivalent of gravels of the interior and to the north; whilst the Upper Boulder Clay (and Hessle Clay) was formed by the retirement of extra-British ice and the increase of that from the Pennine high land. Mr. Lamplugh also presented a final list of mammals and shells from the ancient sea beach of Bridlington, which is earlier in date than the first glaciation of the Yorkshire coast. In connection with local glacial work may be mentioned Dr. Crosskey's report on erratic blocks; he exhibited a fine map of the distribution of the principal boulders in the Midlands, gave lists of boulders from Warwickshire, Lancashire, Cheshire, Isle of Man, and Yorkshire, and attributed their deposit to at least two distinct periods; Mr. Kendall's note on the occurrence of Eskdale and Scotch granites and local rocks in the glacial drifts of the Isle of Man; the account of the boulders of Scotch and Cumbrian granites and other rocks from the Cheshire area by Messrs. Antrobus and Hatch; and a paper by Mr. E. Jones describing the find of neolithic burials in the Elbolton cave near Skipton.

Taking the more general papers in order, we come to two papers by Dr. Hicks, one on earth-movements and their effects on Archæan and Lower Palæozoic rocks in Wales and Shropshire, and a second on the contents of Cambrian conglomerates, which provoked some discussion. In the latter he identifies twenty types of fragments, many of which must have been derived from Archæan rocks, while in the former he attributes many phenomena to earth-movement, which have often been put down to intrusion. Mr. Morgan noted the occurrence of Llandovery rocks in Montgomeryshire, and Mr. Watts correlated so far as possible the Silurian rocks of the Long Mountain with those of the typical Silurian areas of Wenlock and Ludlow. An important paper, establishing correlations in the Devonian rocks of South Devon and Cornwall, was read by Mr. Ussher, and one on an unconformity involving the absence of two zones in the Upper Lias of Bridport, by Mr. J. F. Walker. Mr. Whitaker suggested that trials for coal in the south-east of England might well be made in such localities as St. Margaret's, Chartham, Chatham, Bushey, and Coombs, where borings had already given some idea of the thickness and character of the secondary rocks. Mr. G. H. Morton showed that the Liverpool Bunter was 1950 feet in thickness and the Keuper, of which only the lower part is exposed, 800 feet; two important pebble beds

occur in the succession. Mr. A. Irving dealt with the chemical and geological characters of the Bagshot sands, their bedding, and fossils, and argued that they must have been deposited in an estuary opening on the sea.

Chief amongst the palæontological papers must be placed Prof. Marsh's restorations and descriptions of the Ceratopsidæ, of the skulls of which he exhibited life-size diagrams, some more than six feet in length. Prof. Seeley gave a description of the mural arch in the Ichthyosauria from Liassic and Oolitic specimens. Mr. Smith Woodward exhibited five examples and plates of fishes from the Hawkesbury series, and, on behalf of Prof. Anton Fritsch, plates and descriptions of Palæozoic Elasmobranchs, while Dr. P. H. Carpenter, dealing with the morphology of the Cystidea, compared them with the Crinoids and Blastoids, and suggested that in forms without a genital pore the anal pyramid may have subserved generative functions, while in two forms a fourth opening may possibly have been nephridial in function.

With the exception of local papers, petrology was thinly represented. Mr. Hunt read a paper on the saline inclusions of the Dartmoor granite, and favoured the idea of their derivation from the sea; and Mr. Brindley gave a useful account of the principal marbles of the Mediterranean—a pendant to Sir Lambert Playfair's address to the Geographical Section. Other foreign papers were, one on the geology of Nicaragua, and a second on human footprints in recent volcanic mud in the same area, by Dr. J. Crawford, an account of the minerals of New South Wales, including coal, gold, silver, tin, copper, antimony, iron, diamonds, and ornamental stones, by Mr. C. S. Wilkinson, and a paper on the seismic origin of the "Barisál Guns" of the Gangetic delta, by Mr. T. La Touche.

There only remain to be mentioned, Dr. Tempest Anderson's photographs and descriptions of landslips and volcanoes in Iceland; Mr. Logan Lobley's paper containing an estimate of the gold scattered through the pyrites in the clays and chalk of south-east England; Mr. Hart on volcanic paroxysms; and a paper by Mr. Browne on historical evidences for changes of sea and land levels in the south-east of England.

MECHANICS AT THE BRITISH ASSOCIATION.

THERE was a full programme in Section G at the recent meeting of the British Association at Leeds. It is questionable, however, whether quantity was not obtained somewhat at the expense of quality. We are aware of the great difficulty there is in regulating the supply of papers in the Mechanical Section, and so long as the present mode of procedure remains in force the difficulty will also remain. There should be a limit to the number of papers to be read, and there should be a fixed day on which contributions might be sent in. The day being fixed, it should be adhered to with absolute severity—not the names of all the professors and all the science-knights should suffice to break the law. The papers that were deemed most worthy would be accepted, whilst those with less merit would be returned with thanks. This would create a competition amongst contributors, and would-be contributors, which would, we are sure, have a most healthy influence on the proceedings of the Section. We do not make these remarks simply by the way; the fact is, the proceedings in Section G are becoming of a scrambling and hap-hazard character. It is not long since that one gentleman in this Section read a paper he had previously read before the Institution of Naval Architects. He did not take the matter and re-dress it, but calmly read from the proceedings of the latter society, word for word. This year we have had a great deal of matter that has already appeared in some of the technical journals. The discussions on the papers were, as a natural consequence, generally of a poor description. There was so much to get through that the president was obliged to be constantly hurrying, and any one who was not of the elect was treated with somewhat scant ceremony. As no one knew what the papers were to be about, the most that could be said as a rule was of a superficial and commonplace character, some of the most noted exponents of this school of discussion being especially to the fore. It is very certain that, unless Section G sets its house in order, the mechanical science of the British Association will become a byeword amongst engineers. When one contrasts the scant and listless audience at Leeds last week with that at a meeting of the Institution of Civil Engineers, or of the Institution of Naval Architects—the meetings of the latter are more akin to those of the British Association—one cannot but feel that there is need for very radical reform. The two chief reforms we would suggest would be that a limit should be put to the number of contributions, and that abstracts should be printed in good time and copies be previously sent to members and associates on application. The former would raise the quality of the papers—because that which every one can get no one values—whilst the latter would raise the quality of the discussions.

There were thirty items on the five days' programme in Section G, namely twenty-seven papers, two reports of Committees, and the Presidential address of Captain Noble. The proceedings commenced at noon of Thursday the 4th inst., a later hour than usual being selected in order that the members of the mechanical section might hear the Presidential address of Dr. Glaisher in the Mathematical and Physical Section. Captain Noble's address we have already printed in full.

The first paper on the list was by Mr. J. F. Green, of Blackwall, and was entitled "Steam Life-Boats." The historic firm at Blackwall Yard have at last succeeded in solving a problem, oft attempted but never before with success, and have produced a steam life-boat which has given satisfaction to the Royal National Life-boat Institution. The vessel is driven by the reaction of a stream from a turbine, a mode of propulsion which certainly finds a useful position for life-boat work, whatever may be its shortcomings in the matter of mechanical efficiency. The boat has been placed on the Harwich station, and gives, we think, every promise of success. The great question is undoubtedly that of expense, first cost of boat and cost of upkeep. That however is a matter to be settled by Messrs. Green and the Life-boat Institution. We would suggest that this boat might be improved by the use of liquid fuel on the principle adopted by Messrs. Doxford, of Sunderland, and applied by them to the big torpedo boat they have recently constructed. We know the danger of including too many experiments in one vessel, but now that Messrs. Green have proved their design so far they might venture a step further; and we can speak as to the practicability of the liquid fuel system in question.

"The Victoria Torpedo" was the title of the next paper, which was contributed by Mr. G. R. Murphy. This weapon, which, like all other torpedoes, is to beat everything that has gone before in murderous potentiality, has not yet assumed tangible shape, but the form it is to take when completed was fully illustrated and described in the columns of one of our technical contemporaries a few weeks ago. A paper on aluminium bronze, which calls for no special comment, came next, and was followed by one of the most interesting contributions to the section, in the shape of a paper by Prof. Barr and Dr. Stroud, on new telemeters and range finders. Without illustrations we could not give a fair description of the ingenious instruments, in which the authors of the paper have applied certain mathematical laws to judging of distance, and we will therefore leave the subject for a future occasion.

On the following day, Friday, the 5th inst., the proceedings commenced with the reading of two reports of Committees, namely the Estuaries Committee, and the Graphic Methods Committee. Both these were very brief, and consisted in substance in saying that the work was still progressing. A paper on the manufacture of netting from sheet metal dealt with a process already described in a technical journal. A number of short slits are made in a sheet of metal by a special shearing press, and the slits are opened out so as to form a number of diamond-shaped holes. The invention is ingenious, and the "netting" possesses the great merit of rigidity. Cable tramways next occupied the attention of the Section; Mr. W. N. Colam reading a paper in which he described certain devices which he has devised in connection with this means of dealing with passenger traffic. The "Serve" tube and the simplex brake were the subjects of two papers by Mr. W. B. Marshall. The former is for boiler tubes, and has ribs of metal running the whole length of the interior of the tube. These ribs extend down into the stream of hot gases, and so absorb much of the heat that would otherwise go to the uptake. Of course the heating surface of the tube is much increased, and this is effective heating surface, as the resistance to absorption is greatest at the surface. The Thorne Type Composing Machine, which next came before the Section, appeared to us as an old friend which we think made its *début* in Europe at the American Exhibition, if not before, and was duly illustrated and described in the technical journals of the day. The Bénier hot air motor had

also previously made its appearance in an engineering publication, but the contribution of Mr. Vernon on this subject was taken as read.

On Saturday, the 8th inst., only three papers were taken. Prof. A. Lupton read a contribution on the pneumatic distribution of power; in the course of which he gave some interesting details of the important system which is now working at Birmingham. This paper gave rise to a good discussion, in the course of which the author was sharply taken to task for the efficiency he claimed for the system. It should be pointed out, however, that Mr. Lupton did not speak of "efficiency" as looked at from a scientific standpoint, but from a commercial point of view, which enabled him to take credit for certain waste heat, not obtained from the power installation, which would otherwise be thrown away. This was plainly stated in the paper. Mr. F. G. M. Stoney's paper on the construction of sluices for rivers, &c., was next read. The subject was of course well treated by the author, and the paper was acceptable; but there was little novel in it, except the reference to the new tilting sluices which are to be put up in connection with the new lock at Richmond. Mr. Cope Whitehouse's paper on the Raiyan reservoir was listened to by a thin audience, the preparation for the afternoon's excursions calling the majority away.

Monday in Section G is now given over to applied electricity, and there is invariably a large influx of the more abstract A's into the section. The Leeds meeting was no exception to this rule, and when Sir William Thomson opened the proceedings by reading his paper the People's Hall, which the section occupied, had quite a crowded appearance. The subject which first occupied Sir William's attention was the new electric meter which he has recently brought out. This apparatus is yet in the experimental stage. Perhaps Sir William will be able to do something towards cheapening the design. An example of the meter was shown in operation on the platform. In the discussion which followed, Prof. Fleming made some pertinent remarks on the effect of rough and smooth surfaces. The multicellular voltmeter and the engine-room voltmeter described by the author had previously been brought before the public through the medium of technical literature. A new form of voltapile, also described, was an instrument which was intended for standardizing operations. Mr. Gisbert Kapp described the Lineff system of electric traction, by means of which a partially buried conductor can be used with safety to man and beast. Messrs. Lawrence and Harries next read a paper on alternate *v.* continuous currents in relation to the human body. No doubt at times the effect of electrical currents on the human body possesses a very intense interest for engineers, nevertheless the paper was hardly suitable for the Mechanical Section. It is well, however, that engineers should remember, as was stated in the paper, that not voltage only, but current strength is the important factor in estimating the danger from accidental contact. In the discussion which followed, the late American execution naturally occupied a prominent place. Mr. Wilson Hartnell brought the meeting back to a more mechanical complexion by reading a paper on electric lighting and fire insurance rules, illustrating his remarks by practical examples. He succeeded pretty conclusively in showing that the fire insurance companies want instruction in electrical matters, and, we think, at the same time, he surprised some of those present, who certainly have had considerable experience in electrical matters, by the result of his experiments. The paper was eminently practical and worthy of study by engineers. The last paper on the list for the day was by Mr. W. J. S. Barber Starkey on secondary batteries, in which the author described his system of adding carbonate of soda to secondary batteries. The subject is not new.

Tuesday, the 9th inst., was the last day on which Section G met. Mr. Preece first occupied about five minutes in reading a short contribution on submarine cables for long distance telephony. Mr. F. Higgins next exhibited the "Column Printing Machine," after which Mr. Arthur Greenwood read his paper on heavy lathes. Mr. W. Bayley Marshall followed with a suggestive paper on factors of safety, in which he gave the results of a large number of tests of iron and steel extending over a period of five or six years. The conclusion he had come to was that in roof and bridge work elastic limit, and not ultimate tensile strength, should be the important factor, but in the discussion that followed, which was the best discussion during the meeting, the pertinent question was raised as to what "elastic limit" is. A paper by Mr. J. H. Wicksteed on the measurement of elongation in test samples was also well discussed. A paper by Mr. A. Mallock, on the measurement of strains, in which the author described an instrument he had devised for the purpose, and an exhibition by Prof. Barr of a mechanism for giving vertical motion to a camera, brought the business of the Section to a close.

SCIENTIFIC SERIALS.

American Journal of Science, September.—Rocky mountain protaxis and the post-cretaceous mountain-making along its course, by J. D. Dana.—The magneto-optical generation of electricity, by Dr. Sheldon. It is well known that, by using proper conditions, a beam of plane polarized light may be rotated by an electromagnet, and that a reversal of the current causes the plane to be rotated in the opposite direction. A rapidly alternating current thus produces a rapid swinging to and fro of the plane of light. The author has conducted the converse experiment, and by oscillating the plane of polarization through 90° about 300 times per second, has produced an alternating current.—Contributions to mineralogy, No. 49, by F. A. Genth, with crystallographic notes by S. L. Penfield. The results are given of the examination of some specimens of ferric sulphate from Mina de la Compania, Chili.—Chalcopyrite crystals from the French Creek Iron Mines, St. Peter, Chester County, Pa., by S. L. Penfield.—Koninckina and related genera, by Dr. Charles E. Beecher.—The effect of pressure on the electrical conductivity of liquids, by C. Barus. It is shown that, both in the case of mercury and a concentrated solution of zinc sulphate, the effect of isothermal compression is a decrement of resistance nearly proportional to pressure, and from this fact the deduction is made that the immediate effect of rise of temperature is a decrement of specific resistance.—Notice of two new iron meteorites from Hamilton County, Texas, and Puquois, Chili, by Edwin E. Howell. Analyses of the two meteorites are given.—The Cretaceous of Manitoba, by J. B. Tyrrell.—On mordenite, by Louis V. Pirsson.—Geology of Mon Louis Island, Mobile Bay, by Daniel W. Langdon, Jun.—On Leptænisca, a new genus of Brachiopod from the Lower Helderberg group, by Dr. Charles E. Beecher.—North American species of Strophalosia, by the same author.—Notes on the microscopic structure of oolite, with analyses, by Erwin H. Barbour and Joseph Torrey, Jun.

L'Anthropologie, sous la direction de MM. Cartailhac, Hamy, et Topinard, tome i., Nos. 3 and 4 (Paris, 1890).—The exotic races at the Exhibition in Paris, 1889, by MM. Deniker and Laloy. In this report the authors give the general results of the anthropometric determinations they obtained from their examination of 145 individuals belonging to the most different races, some of which had not previously been made the subject of scientific inquiry. The value of their remarks on the various Senegalese and other South African negroes is enhanced by an admirable series of portraits, copied from spirited photographs by Prince Roland Bonaparte. From the observations of the authors, it appears that the negroes of West Africa may be divided into three or four groups, differing in physical characters. In fact, crispness of the hair, and a more or less dark coloration of the skin, seem to be the only characteristics common to all. The negro races generally are tall, have flat noses, and are of a dolichocephalous type, each group presenting, however, certain features which distinguish them from the remainder. The two leading varieties are separated by tribes which are small in stature, with a very hairy skin, and are of a marked brachycephalic type. This intermediate group is spread across Africa from the extreme east to the west, in about 2° S. and 3° N. of the equator, and it is among these peoples that the true pygmy tribes are found, which under the name of Akkas or Tiki-Tiki of the Nile, Batus of the Congo, Akoas of the Ogowe, have become known to us through Stanley and other recent explorers. According to Emin Pasha, to whom we are indebted for the few particulars that we know regarding their physical character, the mean height of these so-called negrilloes is 1·36 m., and their mean cephalic index 79; brachycephalism being a marked character in all the pygmy tribes. Very complete tables are given by the authors.—New explorations at Solutré, by M. A. Arcelin. Palæontologists will welcome the report here given of the various explorations that have been in progress at Solutré since these important deposits were first made the subject of scientific inquiry in 1866. The extent of the beds, which at some points are fully

ten metres in depth, has retarded the work, which is of a complicated nature in consequence of the different groups of materials that have been brought to light, and which include two distinct *foyers*, belonging the one to the reindeer age, and the other to a probably earlier period, besides numerous sepulchral remains and several accumulations of the bones of horses. The latter are perhaps the most curious of the Solutré finds, since within an area of about 4000 metres there is a circular embankment constructed of horse-bones so densely packed that it is estimated to contain the remains of no less than 10,000 animals. According to the author, these bone-mounds may be regarded as the *kökken möddings* of the early men of Solutré, whose principal food must therefore have been horse-flesh.—A note on two Phœnician skulls found in Tunis, by Dr. Bertholon.—Art among the barbarian races at the fall of the Roman Empire, by Baron J. de Baye. The author shows how greatly archæology has gained in recent times by the researches of French and other men of science in regard to art among the barbarian nations. In France the Abbé Cochet, by his clear definitions of the distinctive features of industrial art among races of Burgundian and Frankish origin, has given a new and firm basis to mediæval archæology, and to him we are indebted for several very important works on the forms and symbolical character of barbaric ornamentation, which is now shown to be common to peoples of the most widely separated countries. The present article is copiously illustrated with drawings of buckles and other ornaments presenting symbolical designs, which have been found not only in Central Europe, but in Russia, the Crimea, and Northern Caucasia. From a careful study of these objects, which have ordinarily been referred to as specimens of Gothic art, it would appear that so-called Gothic forms of ornamentation have an eastern origin, and were gradually vulgarized by barbarian tribes in their passage westward.—A history of the so-called Oppidum de Castel-Meur en Cléden (Finistère), by Paul du Chatellier.—The muscles of the face in a negro of Ashantee, by Dr. Popovsky. This case, according to the author, supplies an instance of the interlacing of the facial muscles, which is not unfrequent among the inferior races, and belongs to a class of anomalies presenting a strongly-marked character of atavism.

Bulletin de l'Académie des Sciences de St. Pétersbourg, nouvelle série, vol. i., Nos. 2 and 3.—The chief papers (in French or German) are:—On the normal variations and the perturbations of magnetical declination, by H. Wild.—On some (seven) species of Russian and Siberian earthworms, by N. Kulaguin.—New contributions relative to the *Olenellus mickwitzi* from the Lower Cambrian deposits of Esthonia, by Fr. Schmidt.—On the quantitative determination of antimonium and sodium, by F. Beilstein and O. Blaese.—A formula for the computation of the length of the arcs of longitude upon the earth ellipsoid, by A. Bonsdorff.—The bases of a mathematical theory of the interior diffusion of light, by Dr. O. Chwolson. The general solution of the problem is not possible; but, on the hypothesis that the interior diffusion of light in a transparent body is due to particles of matter which reflect the light, and can be considered as independent sources of light, the author, after having established the general theory, discusses several special cases in which the problem appears simplified to some extent.—Sahidic fragments of the Bible, by O. Lemm.—Fishes from the Lower Silurian deposits, by J. Rohon. The little hooks, described by Pander as "Conodonts," which formerly were taken for teeth of fishes, but are now considered to have belonged to Annelids and *Gephyreæ*, are accompanied by real teeth of Vertebrata which wholly differ from them, and prove that fishes were living at the earliest times of the Silurian epoch as well.—Report of the Russian delegates to the Paris Conference upon Metrical Measures, by H. Wild and O. Backlund.—On the ancient Turkish dialects: (1) Seldschuk verses in the Rebab-Nâmeh, by W. Radloff.—Ad Plutarchi quæ feruntur Moralia, by P. Nikitin.—Devonian fishes from the Yenisei, by J. Rohon, followed by remarks upon the spinal cord of Devonian fishes generally.—De scholiis in Sophoclis tragædias a P. N. Papageorgio editis, by A. Nauck.—Preliminary results of his observations made upon the satellites of Saturn by means of the 30-inch refractor, by Herm. Struve. The observations were made for the purpose of determining the orbits of the interior satellites, Rhea, Dione, Tethys, Enceladus, and Mimas, and later on, the dimensions of the planet and its rings.

Memoirs of the Odessa Society of Naturalists, vol. xiv.—On the diffusion of a solution of common salt, by N. Umoff. The experiments were made on the system recommended by Sir William Thomson, by means of glass balls, and the results are given day by day for a period of six months. The result is that the law proposed by Dr. Fick for cylindrical vessels is not yet proved.—On the influence of HCl and metallic chlorides upon the photochemical decomposition of water, by E. Klimenko and G. Pekatoros.—On the excretory organs of the Invertebrates, note by A. Kovalevsky.—On isomery in the thiophene series, by N. Zelinsky. Preliminary report.—On M. Timtchenko's anemograph, which combines an anemometer with a weather-cock, by A. Klossovsky.—On some snow-storms, by the same author.—Catalogue of plants found in the neighbourhood of Kishineff (420 dicotyledons and 84 monocotyledons).—On the peritracheal cells of insects, by J. Pekarsky (with a plate).—On the action of the phosphor-pentachloride upon citric acid, by E. Klimenko and Buchstab.—On the snow-covering of South-West Russia, by P. Pantchenko.—On the Nemertinæ of Sebastopol Bay, by J. Lebedinsky. Description of a dozen species of Nemertinæ, formerly unknown at Sebastopol.—Geological exploration in the peninsula of Kertch, by N. Andrussoff. The Mediterranean Miocene deposits of Kertch belong to a basin of the Miocene sea, which extended from Varna, in the Balkan peninsula, to the Ust-Urt, and was connected in the west with the Miocene sea of Roumania and Galicia by means of one or several straits. A good deal of information supplementing the former explorations of the same author is also given.—On the history of the development of the crab *Eryphia spinifrons*, by J. Lebedinsky; an elaborate paper, illustrated by several plates.—On the excretory organs of some insects, spiders, and myriapods, note by A. Kovalevsky.

Bulletin de la Société des Naturalistes de Moscou, 1889, No. 4.—On the chief properties of meteoric showers, by Th. Bredichin (in French). After having developed in his former articles the idea that the "anomalous" tails of comets give rise to meteoric showers, which, as a rule, may appear annually with varying intensities, the author now examines into those meteoric streams which appear in great multitudes at intervals of several years.—Studies on the palæontology of Ungulata, by Marie Pavloff (in French).—The cosmical origin of naphtha, by W. Sokoloff.—Zoological researches in the Trans-Caspian region, by N. Zaroudnoi (in French). The list of mammals mentioned is now increased to 42 species, and that of birds to 309 species; the short notes about their habitats and modes of life are of the same high character as in the preceding work of the same author.

Geological Annals of the Balkan Peninsula, vol. ii., fasc. 1.—Note on the meteorite of Jelica, by J. M. Žujović. Twelve fragments of this meteorite, which fell on November 19, 1889, were collected; the largest of them weighed 3175 grammes. Its composition resembles that of a trachytic breccia. In an earthy, ash-coloured mass, porphyric elements and angular stony pieces of a dark colour, sometimes 4 centimetres long, are disseminated. The latter seem to be aggregates of crystals, probably of pyroxene. Closer microscopical examination is promised.

SOCIETIES AND ACADEMIES.

SYDNEY.

Royal Society of New South Wales, May 7.—Annual Meeting.—Prof. Liversidge, F.R.S., President, in the chair.—The Report stated that twelve new members had been elected during the year. One honorary member, the Rev. J. E. Tenison-Woods, and one corresponding member, Major-General Sir Edward Ward, R.E., had died, and the total number on the roll on April 30 was 461. During the year the Society held eight meetings, at which the following papers were read:—Annual address, by Sir Alfred Roberts. (1) Note on the composition of two sugar plantation soils; (2) well and river waters of New South Wales, by W. A. Dixon. The aborigines of Australia, by W. T. Wyndham. (1) Note on the recent rainstorm; (2) the source of the underground water in the Western Districts, by H. C. Russell, F.R.S. On the high tides of June 15-17, 1889, by John Tebbutt. List of the marine and fresh-water invertebrate fauna of Port Jackson and the neighbourhood, by T. Whitelegge. The eruptive rocks of New Zealand, by Prof. F. W. Hutton. On the application of prismatic lenses for making normal-sight magnifying spectacles, by P. J. Edmunds. Flying machine memoranda, by L. Hargrave. Irrigation in its relation to the pastoral industry of New South Wales, by H. G. McKinney. (1) The analysis of

prickly pear; (2) on the occurrence of arabin in prickly pear (*Opuntia braziliensis*), by W. M. Hamlet. Personal recollections of the aboriginal tribes once inhabiting the Adelaide Plains of South Australia, by E. Stephens. Aids to the sanitation of unsewered districts (poudrette factories), by J. Ashburton Thompson, M.D. Brux. Notes on Goulburn lime, by E. C. Manfred. Notes on some New South Wales minerals, by C. H. Mingaye. The Australian aborigines, by Rev. J. Mathew. The Medical Section held seven meetings, twelve papers were read, and numerous exhibits shown; the Microscopical Section held six meetings. The Clarke Medal for the year 1890 had been awarded to George Bennett, M.D. Univ. Glas. The Society's Bronze Medal and money prize of £25 had been awarded to J. Whitelegge, Sydney, for list of the marine and fresh-water invertebrate fauna of Port Jackson and neighbourhood; also to Rev. J. Mathew, Coburg, Victoria, for paper on the Australian aborigines; and the Council has since issued the following list of subjects with the offer of the medal and £25 for each of the best researches if of sufficient merit:—To be sent in not later than May 1, 1891: The meteorology of Australia, New Zealand, and Tasmania. Anatomy and life-history of the Echidna and Platypus. The microscopic structure of Australian rocks. To be sent in not later than May 1, 1892: On the iron ore deposits of New South Wales. On the effect which settlement in Australia has produced upon indigenous vegetation, especially the depasturing of sheep and cattle. On the coals and coal-measures of Australia.—The Chairman read the Presidential address, and the officers and Council were elected for the ensuing year, Dr. A. Leibius being President.

PARIS.

Academy of Sciences, September 15.—M. Duchartre in the chair.—On the atomic weight of gadoline, by M. Lecoq de Boisbaudran. The author finds that the atomic weight of gadoline is 155·95, which agrees fairly well with the value 156·75, found previously by M. de Marignac.—Observations of the new minor planet discovered by M. Charlois, made at Paris Observatory, by M. G. Bigourdan. The nights of observation of position were September 11 and 12.—Observations of Denning's comet (1890, July 23), made with the great equatorial of Bordeaux Observatory, by MM. G. Rayet, Picart, and Courty. Some observations of position are given which extend from August 5 to September 12.—Solar phenomena observed during the first half of 1890, by M. Tacchini. (See Our Astronomical Column).—The shooting-stars of August 9 and 11, 1890, observed in Italy, by M. P. Denza. (See Our Astronomical Column.)—The tornado-cyclone of August 19, 1890, by M. L. Gauthier. The author thinks that the storm of August 19 should be called a tornado-cyclone, because of its complex character. He gives an account of secondary phenomena that accompanied it, viz. electrical manifestations, divisions of the principal branch, the conical form of the cloud, the aspiration produced by the rapid whirling of the air, and the formation of a lateral wind.—The storms of the month of August 1890, and the solar period, by M. Ch. V. Zenger. The author traces a connection between August storms, the Perseid meteors, and the sun-spot period.—On the acetic ester of acetal, by M. A. Combes.—On the *Isonandra Percha* or *Isonandra Gutta*, by M. Serullas. The author gives an account of the *Isonandra Gutta*, both as to its discovery and as to the growth of certain specimens. Some interesting information with respect to the use of gutta-percha for commercial purposes is also given.—Researches on the propagation of the vine by cuttings, by M. L. Ravaz.—Notes were also submitted by MM. Dumoulin-Froment and Doignon on the electrical gyroscope designed by M. Trouvé for the rectification of the compass; and by M. Mathieu Plessy, stating that he had discovered potassium in the supposed new base that he obtained by heating ammonium nitrate (*Comptes rendus*, August 25, 1890).

BRUSSELS.

Academy of Sciences, August 2.—M. Stas in the chair.—On the preservation of oxyhæmoglobin when sheltered from the action of atmospheric germs, by M. Léon Fredericq. In a note published in the *Bulletin de l'Académie*, No. 2, 1890, the author recorded that oxyhæmoglobin may be preserved intact for more than a month without losing its oxygen, and without being transformed into methæmoglobin, by isolating it from the action of atmospheric germs. He has since found that the oxyhæmoglobin cannot be preserved for an unlimited period, but after a time begins to pass into methæmoglobin, and the transformation is complete at the end of a few months. It appears, in fact, that oxyhæmoglobin preserved in a sealed tube and containing atmospheric germs is transformed entirely into reduced hæmoglobin in a few days. If, however, such germs are rigorously excluded, the oxyhæmoglobin is preserved intact for a much longer period, but at length is transformed into methæmoglobin.—On the characteristic property of the common surface of two liquids in contact, by M. G. Van der Mensbrugghe.—On the reduction of invariant functions, by M. Jacques Deruyts.—On conjugate cubical involutions, by M. Cl. Servais.—Some facts with respect to aldehyde, by M. Maurice Delacre. The author brings some facts relating to the dissociation of chloral hydrate to explain why it should be a well-defined and stable compound, whilst aldehyde hydrate is unknown in an isolated state.—On the deformations produced at the surface of a hollow metallic hemisphere by the impact and by the pressure of a hard body, by M. H. Schoentjes.—Reduction of nitrates by sunlight, by M. Emile Laurent. The author has found that a solution of potassium nitrate exposed to the sun behaves as if it contained a nitrite. It has therefore been concluded that the nitrate is reduced to nitrite by the action of sunlight. Griess's reaction was employed for the identification of the nitrites.—On the reduction of nitrates by brewers' yeast and by some Mucorini, by the same author. From a series of researches it has been found that grains of barley and maize sterilized and placed in sterilized water until the shoot was one centimetre long, contain no bacteria in their tissues, and therefore have not the power to reduce nitrates. Hence the author considers the reduction of nitrates as a property common to certain microbes, and to the cells of superior plants which are developed in a medium containing no oxygen. The researches have reference to some observations made previously by M. Jorissen.

CONTENTS.

THURSDAY, OCTOBER 2, 1890.

THE METAL OF THE FUTURE.

Aluminium: its History, Occurrence, Properties, Metallurgy, and Applications, including its Alloys. By Jos. W. Richards. (London: Sampson Low and Co., Ltd., 1890.)

As the recent improvements in the manufacture of aluminium have been so great as to enable it to be bought now at one-tenth the price it was only three years ago, and as its uses, especially in its alloys, are becoming constantly more extended and varied, a somewhat detailed review may be of service in directing attention to this, the latest book on the subject. It is intended by the author, who is instructor in metallurgy in Lehigh University, to lay before the general public as well as before metallurgists a full and accurate account of the aluminium industry as it exists at the present time. To do this, the author has found it necessary to make such numerous and extensive additions to the first edition, that the present volume may almost be regarded as a new book.

Passing in review the various parts of the book, we come first to an admirable *résume*, of 27 pages, of the history of the progress made in reducing aluminium metal; it contains much interesting information, not easily obtainable elsewhere, describing the founding of the various works for this manufacture from the time of Deville to the present electrical processes of Cowles, of Lockport, New York; of Hall, of Pittsburg; and of Heroult, of Neuhausen, Switzerland. The affairs of Frishmuth, of Philadelphia, here mentioned, may serve as a warning to those too ready to believe reports of success from enthusiasts or from the inventors of secret processes.

Chapter ii., of 7 pages, deals with the occurrence of the compounds of aluminium in Nature. It may be interesting to remind the reader of the existence of several precious stones that contain aluminium, but a list of "some other compounds occurring frequently" is surely very misleading when it contains the minerals turquoise, lazulite, wavellite, topaz, and even cryolite; these ought to have been replaced by such minerals as the sodium- and potassium-felspars, hornblende, augite, mica, kaolin &c. These common aluminium minerals are described, curiously enough, however, in the chapter dealing with the artificial preparation of aluminium compounds. The statement "that aluminium has never been found in animals or plants" requires correction. The description of beauxite is accompanied by many analyses; but that of cryolite, which is directly used in the manufacture of aluminium, is accompanied by an incorrectly calculated percentage composition, and the one statement that "the so-called pure article was found by Prof. Rogers, of Milwaukee, to contain 2 per cent. of silica and 1 per cent. of iron," although further details are to be found on several other pages of the book.

Chapters iii. and iv., of 31 and 13 pages, deal with the physical and chemical properties of aluminium. A list is given of analyses, and an account of various specimens of commercial metal, showing the amount of the impurities, iron and silicon, that may be contained, and the effect on the physical properties is mentioned. The chapter on the chemical properties concludes with a paragraph headed "General Observations on the Properties of Aluminium"; this, being a quotation from Deville's general theoretical considerations, is very much behind the time indeed, and should be replaced by observations made with respect to Mendeleeff's classification of the elements, and coupled to the general considerations on the "structure of aluminium compounds" that introduces the next chapter.

Chapter v. describes generally the properties and preparation of aluminium compounds, but requires some alterations; thus, on p. 86 we read, "Alumina forms no carbonate," and p. 103 is a paragraph headed "Aluminium Carbonate," describing the preparation of the compound $Al_2O_3.CO_2$; and again, p. 88, we find diaspore is $Al_2O_3.H_2O$, beauxite is $Al_2O_3.2H_2O$, and gibbsite is $Al_2O_3.3H_2O$, whereas on p. 47 it is said that "beauxite is a combination between diaspor, $Al_2O_3.3H_2O$, and brown hematite, $Fe_2O_3.3H_2O$," and on the same page is also found "Diaspore, $H_2Al_2O_4$." We must certainly disagree with the names "aluminium-ammonium chloride" for the substance $Al_2Cl_6.3NH_3$, and "aluminium fluorhydrate" for $Al_2F_6.7H_2O$, and also think that the description of some dozen substances as the double chlorides of aluminium and sulphur, phosphorus and selenium, the above ammonia compound and the selenide and selenite of aluminium, might have been entirely omitted, and the space devoted with advantage to a more detailed description of the really important compounds.

Chapter vi., of 29 pages, is a well-written account of the "Preparation of Aluminium Compounds for Reduction," and describes the preparation of alumina from crude sulphates, from beauxite and from cryolite, the preparation of aluminium chloride, and aluminium sodium chloride, and the preparation of artificial cryolite and of aluminium fluoride, and also that of the sulphide of aluminium. The numerous processes here described give one much food for thought and comparison, and though no author is really responsible for the statements of others which he may introduce, yet where the statements of two authorities do not agree, the disagreement should be mentioned and suggestions made to explain the cause of it. Two cases may be cited. On pp. 113 and 118, analyses are given of alumina precipitated by carbonic acid from sodium aluminate solutions: the one shows 2·5 and the other 20 per cent. of sodium carbonate. Again, on p. 121 we find the method of Sauerwein for preparing alumina from cryolite, viz.,

$$Al_2F_6.6NaF + Al_2O_3.3Na_2O + 6H_2O = 2(Al_2O_3.3H_2O) + 12NaF;$$

while on p. 137 is described the very reverse reaction, a method of Berzelius for preparing cryolite from alumina, viz.,

$$2Al_2O_3.3H_2O + 12NaF = Al_2F_6.6NaF + Al_2O_3.3Na_2O + 3H_2O$$

(this last item is a mistake for $6H_2O$).

Chapter vii., of 39 pages, describes "The Manufacture of Sodium," giving a full account of the older processes, and also of the recent ones of Castner and Netto, in which not sodium carbonate, but hydrate, is reduced by carbon at a red heat. There is also reference

made to the experimental preparation of sodium by electrolysis of fused salt.

The eighth chapter, 13 pages, considers "The Reduction of Aluminium Compounds from the Standpoint of Thermal Chemistry." After a short introduction, a list is given showing the heat developed in the oxidation of various metals. At the head stand magnesium and aluminium, and the author predicts the possibility of reducing alumina by magnesium under certain unknown conditions; and it is interesting here to note that C. Winkler, only a few months ago, in the course of a series of logical researches, has found that alumina, heated with magnesium, gives (according to the proportions) either finely-divided aluminium or a hitherto unknown oxide, viz. AlO, a perfectly black substance; and this was the substance for which Deville was searching in 1854, when for the first time he accidentally obtained pure aluminium in globules, an accident which led to his well-known labours in connection with this metal. The chapter concludes with an account of the thermal aspects of the formation and reduction of the chloride and sulphide of aluminium.

The next two chapters, ix. and x., of 26 and 24 pages, are headed, "The Reduction of Aluminium Compounds by Potassium or Sodium," although potassium has probably not been used for the preparation of aluminium since the experiments of Wöhler, in 1845. The first chapter is devoted to the double sodium chloride as source of the metal, and contains very full accounts of the process as practiced by Deville, and of the various improvements made up to the time of Paul Morin in 1882. Describing the patented process of Frishmuth, the author says: "In what the originality of the process consists . . . we cannot see, and we simply acquiesce blindly to the mysterious penetration of our Patent Office Board"; and the remark might fitly be applied to other patents than this particular one, and to other Patent Office Boards than that of the United States. The second chapter describes the reduction of the fluorine compounds. From the experiments and experience of H. Rose, Percy, Dick, Deville, Tissier Brothers, all fully described, the conclusion is drawn that the best use of cryolite is as a flux when reducing aluminium sodium chloride; but as a contrast to this is the account of the Alliance Aluminium Company's processes, by which 77 per cent. of the metal contained in the cryolite was extracted. The account of Grabau's processes, the reduction of aluminium fluoride by sodium, is very interesting, and especially so as he has been the first to produce on a commercial scale aluminium with less than half of 1 per cent. of impurities.

Chapter xi., of 70 pages, is one of the most important chapters in the book. It is an account of the "Reduction of Aluminium Compounds by the use of Electricity," and is introduced by an all too brief review of "the principles of electro-metallurgy as they apply to the decomposition of aluminium compounds." The method of calculating, from the heats of formation, the electromotive forces required to decompose aluminium chloride and alumina having been described, the number of volts thus found are explained to be

"the absolute minimum of intensity which would produce decomposition, and the actual intensity practically required would be greater than this, varying with the distance of the poles apart and the temperature of the bath as far as it affects the conducting power of the electrolyte. From this it would immediately follow that, if the substance to be decomposed is an absolute non-conductor of electricity, no intensity of current will be able to decompose it. If, on the other hand, the substance is a conductor, and the poles are within reasonable distance, a current of a certain intensity will always produce decomposition."

We are sure that such an explanation of phenomena that can only be successfully treated mathematically will not greatly enlighten the uninitiated, and hope that in the next edition the author will find it possible to give a more exact and fuller account of electric phenomena in so far as they apply to the subject in hand; as, for instance, an account of Ohm's law applied to electrolytes, of the chemical and thermal effects of electric currents upon electrolytes, of the chemical, electrical, and thermal effects of secondary reactions to which the products of the electrolysis may give rise, &c., and also even a brief description of the instruments and machines used to measure and generate the powerful currents used in the manufacture of aluminium. With the expression of this hope we will pass over many inaccurate and dubious expressions relating to electrical terms and descriptions.

Exceedingly curious is the account of some twenty patented processes for depositing aluminium or its alloys from aqueous solutions, and the following remarks of the author summarize the results obtained by all these enthusiastic labourers in Nature's unwilling fields :—

"We have inventors affirming in the strongest manner the successful working of their methods, while other experimenters have followed these recipes and tried almost every conceivable arrangement, yet report negative results. . . . No good authority testifies to the success of any process so far advanced, neither have I seen any so-called aluminium plating (from aqueous solution) which really was aluminium."

"The Electric Decomposition of Fused Aluminium Compounds" is treated, with the exception of a few cases, chronologically; in reviewing the chapter we shall, however, group them according to the electrolyte used, and we cannot but think that this very important chapter could have been presented more concisely in such a way.

First, then, there are accounts of the electrolysis of fused aluminium sodium chloride by Deville, Bunsen, Le Chatellier, Berthaut, and Grätzel, whose process was actually tried on a large scale, but abandoned. The processes of Omholt and Faure are amusing, inasmuch as the one melts aluminium chloride in a reverberatory furnace! and the other electrolyzes a bath of the same substance at 300°!

The remaining processes may be classified as follows: (1) electrolysis of cryolite without addition of alumina, but with or without addition of salt, &c.; (2) the same as No. 1, except that alumina is also added; (3) electrolysis of alumina dissolved in cryolite salt, &c.; (4) electrolysis of fused alumina; (5) electrically heating mixtures of alumina and carbon to such a temperature that they react upon each other chemically; (6) methods using crude clay, beauxite, or kaolin as the source of alumina, and not worthy of further consideration. To the first class belong the processes of Gaudin, Grabau, Feldman,

and perhaps also that of Rogers; the products of the action are aluminium and chlorine or fluorine. To the second class may be ascribed the process of Kleiner, perhaps that of Rogers, and that of Bernard Brothers; the products of the action are the same as the first class, but the aluminium fluoride destroyed by electrolysis is in part restored to the bath "by causing the fluorine vapours evolved to act on alumina or beauxite placed somewhere about the anode." To the third class may be ascribed the processes of Henderson, Hall, and part of Heroult's patented process; here the products are said to be aluminium and oxygen, which by contact with the carbon anode is converted into carbon monoxide or carbon dioxide, and the cryolite, &c., used as solvent for the alumina are said to remain unchanged. The fourth class contains only Heroult's process, and of that only the latter half of his claims. The fifth class contains the process of Monckton, Cowles, Menges, and Farmer.

As regards the details of these various processes reference must be made to the book. The processes of Cowles, Hall, and Heroult are reported as being in active and very extensive use by the several companies, and if one is to believe the glowing reports that are published they are very successful indeed; thus Hall claims to extract 50 per cent. of aluminium from alumina, instead of the theoretical 52·94 per cent., while the fluorides used waste only very slightly, and require replenishing to the extent of a small fraction of the weight of the metal made; and with his latest improvements aluminium is not to cost more than half a dollar a pound!

The scientific investigation of these processes is either kept secret, or, alas, has scarcely been attempted; and yet the surest and quickest way to establish a process on a sound commercial footing is to thoroughly investigate the conditions regulating every reaction, and not merely those conditions relating to the principal reaction, for those relating to the ubiquitous "impurity" are at least of equal, if not of greater, importance. In describing the above processes, the author introduces scientific and numerical discussions on several points; but the work would have been more valuable to the increasing number of metallurgists interested in the subject if the book had bristled more with hard facts expressed in figures, and with references to volume and page where the original might be found.

Chapter xii., of 31 pages, is a summary of the very many processes that have been proposed for the "Reduction of Aluminium Compounds by other means than Sodium or Electricity." Many of the accounts record the partial success of actual trials, and deserve consideration; but many are but little more than written hopes and imaginations.

As far as the end of this last chapter, the subject-matter, with the exception of chapters iii. and iv., is purely chemical, and relates, indirectly or directly, to the primary production of aluminium or of certain of its alloys. From this point the book deals with the manner of working aluminium, the preparation of its alloys, and the properties which characterize them. This metallurgical part of the book may be considered as being introduced, as far as aluminium itself is concerned, by chapters iii. and iv. and some four pages of chapter xiii., which describe the "Purification of Aluminium," and refer very briefly to Mallet's preparation of the pure metal. The special methods found suitable for the analysis of aluminium and its alloys are described in the last chapter of the book.

Chapter xiii., of 29 pages, describes fully the methods of working in aluminium—casting, rolling, annealing, soldering, &c., &c. In speaking of the uses of aluminium, the author says, when referring to its lightness,

> "but I would say a word or two about the popular fallacy of aluminium replacing steel as a constructive material, . . . or in any position where its strength is of importance, . . . it is forgotten that it is only one-third as strong."

The aluminium alloys are considered in the next three chapters. Chapter xiv., of 30 pages, describes many alloys, of which the following two classes are especially important, as they promise to enter largely into commerce. The alloys with copper and nickel mostly contain but a very small proportion of aluminium, but nevertheless are superior to ordinary German silvers for strength and fineness of grain. Those containing copper and zinc, and known as aluminium brass, possess exceedingly valuable working qualities, are three and four times as strong as ordinary brass, and containing mostly only 2 or 3 per cent. of aluminium are further recommended by their low cost. Chapter xv., of 32 pages, describes the alloys with copper; of these the most important contain 5 or at most 10 per cent. of aluminium, and are known as aluminium bronzes; and full accounts of the methods of working and tests of the strengths of the metals are given. Chapter xvi., of 31 pages, describes the "Aluminium-Iron Alloys," and is a very interesting account of a difficult but exceedingly important subject. The chapter is divided into three parts, dealing with the effects produced by adding trifling quantities of aluminium to steel, to wrought-iron, and to cast-iron; in almost all cases the castings are quite free from blow-holes; and in certain cases the metal becomes more fluid, allowing of castings being more readily made. Cast wrought-iron sounds like a paradox, but it is not one, for, by adding a small amount of aluminium to wrought-iron that has been heated until it has become pasty, the latter immediately liquefies, and can then be poured into moulds, making castings as sound as if they were of grey cast-iron. The author discusses at some length the probable explanations of the effect of adding aluminium to the various kinds of iron, and his conclusions may be very briefly stated as being: (1) addition of very small quantities of aluminium, *i.e.* 0·01 to 0·1 per cent., causes the destruction of carbonic oxide or dioxide, or of the oxygen compounds, as oxide of iron, disseminated mechanically, and which at the moment of setting give rise to the formation of these gases; hence the cast metal is free from blow-holes, and, owing to the removal of suspended oxides, the metals cease to be pasty and become quite fluid; (2) addition of aluminium in larger quantity, *i.e.* 0·2 to 0·5, or even several per cents., converts the combined carbon—that is, if there be any appreciable amount—into graphitic carbon, and, according to the quality of the iron operated on and the amount of aluminium added, has the effect of rendering the castings free from a chilled surface, of making the metal very uniform in texture and hardness, or

of separating the graphite to such an extent that the metal becomes pasty and unfit for making castings. Wonderful, indeed, are the effects of traces of foreign substances on the physical properties of the metals, and, though much has been done towards studying the effect of foreign substances on the properties of iron—the metal of the past, the present, and the future also, notwithstanding all that has been said about aluminium—yet the effects of this new "impurity," aluminium, are so great that evidently not only the modern man of science, but also the time-honoured iron-master, has still much to learn.

H. BAKER.

ELECTRIC DARKNESS.

Electric Light: its Production and Use. By John W. Urquhart. Third Edition. (London: Crosby Lockwood and Son, 1890)

THIS book has the characteristic defect of many scientific works that go through several editions—the old matter is fondly retained, while edition by edition, new bits of information are inserted here and there, until finally the paragraphs must feel as awkward in one another's company as ancient Britons and gentlemen in top hats. And unfortunately Mr. Urquhart gives no hint to the readers of "Electric Light" as to which are his aboriginal paragraphs painted in woad, and which of them wear the modern frock coat.

That section of his book which is devoted to arc-lamps almost starts with a description of the *latest* form of the Brockie-Pell lamp, followed by an account of the Siemens and Hefner Alteneck pendulum and differential lamps, the Thomson-Houston, and the Brush lamps, types which may all be met with in constant use at the present day; then the author, without a word of warning that he is becoming historical, dilates on the Wallace-Farmer and the Rapieff forms. Next comes the Crompton lamp, with only a page given to it, and not thought worthy of an illustration. The reader would hardly gather from this that the Crompton lamp is extensively used in railway stations and elsewhere at home and on the Continent, and that the streets of one of the few towns in England electrically lighted—viz., Chelmsford—obtain their light wholly from Crompton lamps. We have then the description of a very excellent lamp, the Pilsen, especially in view of the improvements introduced into it by Mr. Joel; these, however, are not even referred to, Mr. Joel's contribution to electric lighting being confined, according to Mr. Urquhart, solely to his semi-incandescent lamp of 1881. And the description of the Pilsen lamp only occupies a fraction of the space devoted to the rotatory disc, the Regnier, the Werdeman, the Wilde, the Jamin blowpipe lamp, and other obsolete specimens which close this section, wherein may be found some of the most important arc-lamps of the present day indiscriminately jumbled up with types that figure only in museums and text-books.

Although the book is dated 1890, the description of Sir William Thomson's meters, to which only half a page is given, must have been written several years ago, before Sir William abandoned the use of iron, since, according to "Electric Light," all the assistance Sir William has contributed to the electric light industry is the invention of a voltmeter in which a stumpy bit of iron is attracted by a coil. The co-inventor of the Ferranti dynamo is we learn, another man, a Sir William Thompson, with a "p."

With reference to the Deptford mains we are told, "The main is composed, first, of a copper tube of small diameter surrounded by a considerable thickness of insulating material, the whole being enclosed in a copper or other metallic tube about three inches in diameter. It is to be particularly observed that the 'return' is intended to be put in connection with the earth." We should like to hear what the Postmaster-General would say to this bit of intelligence after the opposition that he offered in the spring of 1889 to the original plan being carried out, and which led to the return of the Deptford mains being insulated.

Details are given of the electric lighting of the Albert Hall by 5 arc-lamps, the author not mentioning that the words, "At the Albert Hall a saving of gas is effected, &c.," and those that follow were written in the very early days of electric lighting. And yet, so anxious to be up to date does the author profess himself to be that he states, when dealing with high candle-power lamps, "We need not enter more deeply into the question how many, because . . . calculations made in 1889 would probably not apply in 1890."

This happy indifference that he displays to the distinction between the past and present tense may very likely lead people to unfairly condemn as useless, and out of date, a good deal of solid and valuable information which the book contains. The chapter on electric distribution is distinctly good, and the chapters on dynamos may be read with profit if we set down to the author's love of living in the past the accounts he gives of the Wallace-Farmer, of the Bürgin, and of other dynamos now practically abandoned; and if we attribute to a like cause such information as the following with reference to direct-current dynamos:—"The idea of making the armature a fixture, and of causing the field magnet to revolve within it, has, . . . in several lately-constructed machines, proved a most advantageous form of construction." The section on the management of the dynamo is particularly useful, and contrasts most favourably with the large amount of historical matter the book contains. We hope, however, that the author's statement regarding a shunt dynamo, as to its probably being impossible to burn up such a machine by short-circuiting, will not be brought forward as an excuse by some beginner for short-circuiting a shunt dynamo which has been running on open circuit; because the bill that will probably have to be paid for rewinding a burnt-up armature will forcibly illustrate the importance of taking into account what the author has neglected, viz. the residual magnetism of the field-magnet cores.

The detailed instructions which are given for making simple apparatus like batteries, a laboratory magneto-Gramme machine, simple arc lamps, &c., will recommend the book to amateurs, but the author's views that the vertical slit down the cylindrical zinc of a cell is for the purpose of preventing local action, that "both sides of the zinc evolve electricity," that "electricity of

opposite name is believed to flow off in contrary directions in equal quantities from the surface of generation, viz. the junction of the liquid with the positive plate," are very crude even for amateurs.

Mr. Urquhart's account of accumulators is a trifle mixed. On p. 47, "the negative grids are filled with litharge;" but on p. 48 we have "the litharge (positive) plate"; the capacity of an accumulator with 32 lbs. of plate is stated to be 50 ampere hours, whereas, as a matter of fact, it is about two and a half times that amount. The specific gravity of the solution, which Mr. Urquhart says should be 1·220 when the cell is fully charged, falls, he says, about 0·1 for every 5 ampere hours, no reference whatever being made to the size of the cell. The specific gravity, then, of the liquid of an accumulator from which 61 amperes could be taken, would fall to nought at the end of the first hour of discharge, though what that might mean we do not know. On p. 51 we are told in connection with the miner's lamp, that an accumulator weighing only 3 lbs. can "be made to light a small incandescent lamp for ten or twelve hours, yielding a light of two or three candles." Now 3 candles for 10 hours means about 120 watt hours, so that, if we assume that the box and liquid weigh together only 8 ounces, this marvellous accumulator stores something like 140,000 foot-pounds of energy per 1 pound of plate. On p. 294 the weight of the miner's accumulator and incandescent has gone up to 7 lbs., and the light has gone down to 1 or 1½ candle.

This sort of looseness runs through the book, "The legal ohm is the resistance presented by a column of pure mercury, 106 centimetres in length and 1 millimetre in section," the word square before millimetre, and all reference to temperature being omitted. After the definition of the watt it is stated that "An incandescent lamp is said to need 4 watts per candle power, or 60 watts in all to run it;" "said to need" looks as if it were a definition instead of being an experimental fact, and since the candle power of the 60 watt lamp is not mentioned, it might appear that all incandescent lamps from 2 to 2000 candles power required 60 watts. In speaking of the number of lamps a dynamo can maintain glowing, the author says, "More lamps could be maintained at 5 watts per candle than at 4;" we should very much like to know why. The phase of an alternate current is defined as its life. Under "Cost of Electric Light" we are told, "The Board of Trade unit, consisting of a kilowatt (a thousand watts for one hour) is the recognized standard of calculation," and that this is not a printer's error is shown by the author going on to say, "that a kilowatt can be sold at a fair profit at from 7*d.* to 9*d.*" Perhaps the author will favour us with the market value of one mile an hour.

A large amount of useful information has been collected together, the illustrations are abundant and well executed, and probably much time has been spent in the compiling of this book. Is it not a pity then that its value, both for the technical reader and for the electrically-lighted householder, should be much diminished by the unscientific vagueness that runs through it, and by the indiscriminate mixture of the antique with the modern in its pages?

COUES'S "HAND-BOOK OF ORNITHOLOGY."

Hand-book of Field and General Ornithology: a Manual of the Structure and Classification of Birds. With Instructions for Collecting and Preserving Specimens. By Prof. Elliott Coues, M.A., M.D., &c. Pp. 344. (London: Macmillan and Co., 1890.)

NATURALISTS are not unfrequently regarded as belonging to two categories—those of "the field" and those of "the cabinet." The "field naturalist" is too often little acquainted with scientific method, and apt to undervalue scientific research. On the other hand, the "cabinet naturalist" in many cases despises the labour of his brother of "the field," and thinks that he can solve all the problems of life without studying the living organisms. The best naturalists—it is not necessary to quote names in support of such a truism—have always been those who combine much experience in the field with great study in the cabinet. The author of the present work is well known to possess both these qualifications, without which, indeed, he could hardly have ventured on the task of writing it. His experience in the field, as he tells us in his prefatory remarks, reaches in time over thirty years, and extends in area over large portions of North America. Having made personal acquaintance with most of the species of North American birds, and having shot and skinned with his own hands several thousand specimens, he may reasonably claim to speak with authority on field ornithology. On the other hand, Dr. Coues is the author of the "Key to North American Birds," which has passed through many editions, and is generally recognized as the standard text-book of the American ornithologist. On this branch of his subject, therefore, Dr. Coues is likewise entitled to claim our full attention.

Dr. Coues commences his hand-book with "Field Ornithology," which, as he truly says, should lead the way to systematism and description, and devotes nearly ninety pages to this part of his work. The necessary implements for collecting, the various instruments and materials required for making skins, the proper modes of registration and labelling, and the right way to keep a collection when made, are all discussed in turn, and admirably explained and illustrated. "Labelling," we are glad to see, Dr. Coues expatiates upon at full length, and it is impossible to exaggerate its importance. How often are the best prepared and rarest specimens of natural objects rendered comparatively useless by the neglect of this requirement! We do not presume to say that all the twelve particulars insisted upon by our author should be given in every case, but the locality, the date, and the collector's name should at least never be omitted from the label of a scientific specimen.

A still more important part of Dr. Coues's hand-book is that of "General Ornithology," which occupies the remainder of the present volume. It is divided into four sections. In the first of these the author endeavours to define exactly what a bird is, and discusses the position of the class "Aves" in the series of Vertebrata. In the second section the principles of classification are reviewed, and it is shown that morphology or bodily structure is the only safe guide to a natural system. The third section is devoted to a description of the external characters of

birds, and the fourth to the internal characters, or, as they are generally called, the anatomy of birds. These two essays form in fact the most important part of the volume, and occupy more than half its pages. Both of them are well drawn up, the various characters are described in plain and simple language, and the structures are illustrated by a large number of woodcuts introduced into the text. That Dr. Coues's statements are absolutely free from error we by no means affirm. Zoological science is progressing rapidly nowadays, and since these essays were written, five or six years ago, discoveries have been made that should have caused a modification of some of them as they now stand. But Dr. Coues is generally well up to the level of modern science, and seems to be acquainted with most recent views of experts on most points. On the whole, we know of no volume likely to be more useful to the student who wishes to become acquainted with birds, alike in the field and in the cabinet, than Dr. Coues's "Hand-book," and we are of opinion that the publishers have done a good deed in reprinting it for the use of British ornithologists. No other manual that we are acquainted with exactly takes its place, or contains such a well-arranged mass of useful and generally correct information on this subject.

OUR BOOK SHELF.

Swanage: its History, Resources, &c. (London: William Henry Everett and Son, 1890.)

Seaside guide-books are generally the production of some local tradesman, but the rising town of Swanage has issued one by no less than eight authors and an editor. Nothing but exceptional care could knit such a work into harmony, yet of editing there is no trace but the name. Though a full chapter by such an authority as Horace B. Woodward is devoted to geology, its interest is allowed to be forestalled earlier in the book by writers who are in apparent ignorance of the coming chapter, and who make no reference to it.

The book contains no itineraries, no suggestions as to how and in what time places of interest can best be reached; no guide as to hotels and lodgings, or tariffs for carriages and boats; no hints as to sea and river fishing; nothing of the birds; not a word on marine zoology. In place of these there are an introduction and conclusion, presumably editorial, worthy of a tenth-rate society paper, the latter containing a table of distances by a literary scaramouch. In this extraordinarily facetious table, Cowes is given as distant 27½ miles by water and 6½ by *land;* the Needles are 19½ miles nearer by *land* than Bournemouth; Parkstone and Poole, though well-nigh suburbs of Bournemouth, are no less than 24 miles nearer by land to Swanage; Bournemouth itself is said to be 34 miles distant, while everyone knows it is only 25 miles by rail; Southampton is actually less distant than Christchurch, and so on. With such editing we are not surprised to find the same place figuring as Branksea in the letterpress and Brownsea on the map.

It is impossible seriously to criticize the anonymous portions of such a book, except to say that the archæological information is evidently by an accomplished antiquary. It is a pity that his solid contributions are interwoven with adulatory remarks, perhaps by the editorial gentleman, which must be distasteful to Mr. George Burt, who, owning some 150 to 200 acres of the best building land "already laid out and ready for erecting residences," no doubt finds his account in what he does.

Of the specialist chapters, that relating to hygiene, by Dr. L. Forbes Winslow, is the longest, and we should have thought 27 pages more than ample to tell us that, being almost on a promontory on the south coast, and well sheltered from the north-east by a high range of downs, the climate of Swanage is mild, equable, and bracing, and with good water and drainage should be particularly healthy. Visitors should be warned, on the other hand, that the air is strong, and that the Purbeck Hill at the back is bleak and bare of trees, and being riddled with stone quarries presents a forbidding aspect.

The chapter on geology is of course excellent, and, had it been illustrated with a few sections and figures of fossils, would be sure to induce visitors with time on their hands to take the subject up. We cannot think, however, that the Wealden has the enormous thickness of over a third of a mile so close to its western limit, and rather believe that the same beds occur over and over again in a series of truncated folds. The author, like others who know the section, does not endorse the views of Prof. Judd on the so-called Punfield Beds. The section deserves notice as the only British locality for a gigantic Paludina, and all the beds up to the chalk are fossiliferous, and deserve more careful investigation than they have received. On the other side of the massive chalk barrier, the Lower Bagshot beds, though only 70 feet thick at Alum Bay, occupy about half a mile of the shore at high angles, and are as obviously plicated as the Wealden. They are so entirely grassed over, except at Redend Point, that nothing can be known of them, but inland masses of Middle Bagshot are present in the folds. The beds are very fossiliferous in places, but the pipe-clays have had such a squeezing, that the leaves are miniature geological models of faults and slickensides, and readily fall to pieces. The vegetation is much more characteristic of swamp life than at Alum Bay, the prevailing fossils being a large fan palm, reeds, and a tropical Chrysodium massed together, and more rarely leaves of *Aralia primigenia, Quercus lonchitis,* Acer and Salix, and occasional shells of Unio and elytra of insects. The poverty of the flora is in contrast with the enormous wealth of that of the Bournemouth beds just across Poole Harbour.

Of the admirable and careful lists of plants by Mr. J. C. Mansel-Pleydell, and of insects by Messrs. Herbert Goss and Eustace Banks, we have nothing to say except to lament that the book is so unworthy of them. Of course there is no index, and the illustrations are commonplace process plates, in which Mr. Burt's house and his big refreshment-room on the hill, perhaps the future Casino, figure prominently. Really interesting bits like the tower of the old church, or romantic scenes like the Pinnacles or Old Harry, are omitted. J. S. G.

Graphic Lessons in Physical and Astronomical Geography. By Joseph H. Cowham, F.G.S. (London: Westminster School Book Depot, 1890.)

The method of teaching adopted in this work justifies itself for the subjects with which it deals. The lessons have been prepared to cover certain courses of instruction, among them being the Standard Code, pupil teachers' course of geography during the four years of their training, scholarship examinations preparatory to entrance into a training college, and for the entire course of physical geography laid down in the certificate syllabus for first and second year's students in training colleges.

The main features of the work lie in its arrangement, the note-like style adopted in the great variety of simple sketches and blackboard illustrations which demonstrate well the innumerable points for which they are required. Each item of matter is surrounded by abundant information, and teaching hints in the form of notes are given here and there for the benefit of those using this book.

The end of each section contains a short summary of the preceding subject matter, and concludes with questions

for examination. The book will be sure to be well used, and we recommend it, and with the authors we hope "that it may stimulate others to make the teaching of physical geography a pleasant exercise for themselves and a valuable mental training for those whom they teach." W.

The Evolution of Photography. (Illustrated.) By John Werge. (London: Piper and Carter; John Werge, 1890.)

IN this work we have a most interesting account, arranged in chronological order, of the origin, progress, and development of the science and art of photography. The author has divided this time into four periods. The first deals broadly with facts bearing on the accidental discovery of photography, and on the early researches and ultimate success of the pioneers. The second embraces a fuller description of their successes and results, while the third is devoted to the consideration of patents and impediments, and the fourth to the final development of both photographic literature and art.

Although the author has not entered minutely into elaborate details of each process, yet he has given enough to form an interesting summary. Excellent illustrations of some of the chief photographic investigators, taken from paintings, daguerreotypes, &c., and reproduced by the callotype process, add greatly to the value of the book.

Following this there is a chronological record of inventions, discoveries, publications, and appliances connected with the development of photography, and the author concludes with the personal reminiscences, extending over a period of forty years.

This book will be an acceptable addition to our photographic literature, and will be found interesting not only by the practical photographer, but by many amateurs. W.

Geometrical Drawing for Art Students. By I. H. Morris. (London: Longmans, Green, and Co., 1890.)

ART students will be glad to find in this work a compendium of those parts of geometry which cover the necessary range for their course. Plane geometry and its applications, the use of scales, and the plans and elevations of solids, are treated concisely, and the method adopted throughout of placing the text on the left-hand pages, leaving the right-hand pages solely for figures, will be found most convenient. The figures are all neat and well drawn, those illustrating the problems on solid geometry being especially so.

The chapter on the construction and use of plain and diagonal scales and scales of chords, subjects which are generally stumbling-blocks to a great many students, is made very clear, and in chapter xv. good ideas are imparted in the applications of geometry to the construction of patterns and simple tracing.

Nearly six hundred figures are inserted in the book, together with a complete and exhaustive collection of exercises. Students interested in this subject other than those for whom the work is intended will find the arrangement adopted more convenient than in many other books on the subject. W.

An Elementary Text-book of Dynamics and Hydrostatics. By R. H. Pinkerton, B.A. Oxon. Second Edition. (London: Blackie and Son, Limited, 1890.)

WE are glad to see the appearance of a second edition of this serviceable little text-book, the first edition of which we reviewed some time ago. No material alteration has been made in any part of the work. The appendix has been extended by the introduction of the method of co-ordinates, the discussion of simple harmonic motion and its application to the pendulum, and the method of finding moments of inertia.

Several new examples have been fully worked out for the purposes of illustrating the methods of solving problems graphically, and some additional examination papers have been given.

At the beginning of the book tables of relative density and of the English and French measures will be found, and the work concludes with a newly added index. We can only repeat what we said formerly, that this is a book to be thoroughly recommended. W.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Pilcomayo Expedition.

IN view of the notice in the *Times* this week of the collapse of the Pilcomayo Expedition, the inclosed extract from a home letter of Mr. J. Graham Kerr, Naturalist with the Expedition, may be of sufficient interest for publication in NATURE. The letter was received in Scotland on September 2. It contains no mention of Captain Page, and must have been written before his death as recorded in the *Times*. The letter bears out the *Times* account of the difficulties encountered by the Expedition, and that the Pilcomayo is not likely to become a trade water-way; but it does not foreshadow disaster such as the *Times* account suggests, and it gives hope that the other members of the Expedition may not have shared the fate of Captain Page. ISAAC BAYLEY BALFOUR.

September 27.

"*s.s.* '*Bolivia*,' *Rio Pilcomayo, lat.* 24° 25′ *S., long.* 58° 40′ *W.*, "*Tuesday, June* 3, 1890.

"We entered the Pilcomayo on March 12, therefore we have been 3 months on the river. We have managed to penetrate about 300 miles by river in that time, but owing to the extraordinary tortuosity of the Pilcomayo, our distance in a straight line from Asuncion I don't suppose is more than, if it reaches, 100 miles. The river is very disappointing from the points of view of æsthetics, botany, zoology, geology, and anthropology. As regards the first, the scenery in the lower reaches is certainly beautiful, but of a type of beauty which soon palls upon one, and becomes intensely monotonous. The scenery is very much that of a sluggish flowing river at home. When we first entered the river, I was amazed at its small size—only about 50 yards in width. Up here it seldom reaches 20 yards, and is frequently not more than 10, and there is scarcely any water in it at all. For the last two months we have got forward not more than 10 leagues, at the very outside, and what little we have done has been by building dams, letting the water accumulate, and so getting forward for a short distance, when another dam was built, and so on. The larger steamer, the *General Paz*, we had to leave far down the river. The military detachment whom we had left a few miles down was discovered the other day to have flown, their provisions, no doubt, having run short. We brought a corporal and two men on with us. The other day, however, one of these deserted, and has, no doubt, either gone over to the Indians or been killed by them. To return, however, to the scenery. Here, and for a long distance down, we have had a type of scenery which is to be found in very few parts of the world—that of an immense palm forest, covering thousands of square miles. It consists typically of a perfectly level plain clothed with breast-high grass, over which are closely studded palm-trees with large fan-shaped leaves; all around; far as the eye can reach, an interminable vista of palm-trees, varied only by an occasional clump of brushwood, or near the river by a small patch of forest. In no way is the aspect of nature suggestive of the tropics here, *i.e.* when one has got over the first impression induced by the palm-trees. The Gran Chaco is in fact an immense wilderness. Large game occurs only in small numbers. I have managed to get only a couple of peccaries, and no one else has shot any large game. I have not even got a tiger yet, and have only once had anything approaching an adventure with one. Other adventures we have had absolutely none. Intense monotony and uninterestingness are the chief characteristics of the river. Botanically speaking, it is

an absolute desert. In an ordinary summer's afternoon walk at home one sees more species of plants in flower than I have seen since we entered the river. . . . However, this may improve, as it is now the dead of winter here, and with the advent of spring I hope to see many new and interesting flowers appear. Zoologically, too, it is disappointing, except in the case of birds. In the lower parts of the river not a bird was to be seen, but now they are rather more frequent, and I have already observed 116 species, of which I believe about 30 have not before been collected in Argentina. Owing to the desert nature of this part of the Chaco, its human inhabitants are very few, scattered, and nomadic. We have not seen a single Indian or canoe on the Pilcomayo. But we know they are about, for nearly every day we see their great fires for hunting all around us, and we occasionally come across a chipped palm, or the remains of an old *tolda*, the rude shelter which serves them as a tent; now and again, too, we see a human footprint, sometimes of immense size, impressed upon the muddy margin of a lagoon. So we are always on the alert, the four Britons of the Expedition keeping watch at night, fully armed and wide awake. The four said Britons are Poole, Kenyon (English), Henderson the chief engineer, and myself. When I go away collecting also, as I do every day, I always go with loaded revolver and knife—ready for emergencies. For in addition to Indians there are abundance of tigers about, which one has to be prepared for. Yesterday we got an alligator close to the boat, 8 feet long. The alligators here are all small, 8 feet being the largest we have seen. . . .

"As regards food we are on very short rations, being within a month or so of the end of our provisions. The canoe is to be sent down soon, I believe, to hurry up the fresh supplies of provisions, and by it I shall send this letter, although it is very doubtful whether you will ever get it. The health of the men is not good; we have always two or three of the 17 on board ill. I have, however, had excellent health. The only thing disagreeable is the fearful cold. In the mornings the thermometer is often nearly at freezing-point, and I feel quite benumbed. Fortunately, it generally gets a little warmer during the day, the temperature rising in the afternoon to between 70° and 90° F. The river-water is regular brine here, quite as salt as sea-water, and when occasionally we run out of fresh water for a few days, it is very disagreeable having to take coffee, &c., made with the salt water. Of fruits here, there are none worth eating. The young parts of the palm-trees are eatable, and we use a good deal of it in order to economize the rice, &c. I don't expect at all that we can possibly reach Bolivia, and I don't think the river could ever be made navigable."

Protective Colours.

MR. POULTON, in his book entitled "The Colours of Animals," seeking a reason for the glistening metallic colours of many chrysalides, after showing that the colour is probably protective in its origin, states "that it has arisen from the protective resemblance to rough dark surfaces of rocks."

He comes to this conclusion after failing to find other more probable examples of glistening bodies in nature.

Are such not, however, very common (i.) in the slime or mucous covering many of the Invertebrata, and which snails and slugs leave on all surfaces over which they have passed; (ii.) the webs of spiders and their allies, especially if moist; (iii.) the exudation or excretion of many plants; (iv.) decomposing bodies; (v.) the bark of many trees?

Perhaps the commonest places to find glistening chrysalides are on palings, tree trunks, and various plants; all of which structures are usually resplendent with one or more of the above metallic hues, and among which the chrysalides are very hard to find.

May not these more common objects be those of attempted resemblance, rather than the less frequent pieces of broken rock?

Grosvenor Club, Bond Street, W. WALTER K. SIBLEY.

MR. SIBLEY's letter appears to me to contain valuable suggestions as to the meaning of the metallic appearance of certain chrysalides. It is probable that a resemblance to the objects he suggests does aid in concealing the pupæ. Mr. Roland Trimen has similarly concluded that certain brilliant beetles (*Cassididæ*) are protected by resembling drops of dew. At the same time I think that there is some evidence that the metallic appearance of the pupæ of *Vanessidæ* may have been originally acquired in order to favour concealment against glittering mineral surfaces. The evidence is as follows:—(1) In shape and character of the surface these pupæ strongly resemble a rough and broken piece of rock. (2) They appear in two forms, resembling grey and weathered as well as freshly exposed and glittering rock surfaces. (3) When they seek green leaves for pupation they either conceal themselves with the greatest care (*V. atalanta*), or a glittering variety of other species is represented by a green variety which is inconspicuous against the leaves (*V. Io*). (4) Another species (*V. urticæ*), which lacks the habit of *V. atalanta* and the green variety of *V. Io*, is, as far as my experience goes, very rarely found on the leaves of its food-plant, and when so found, is, as a rule, diseased.

I mention the chief lines of evidence upon which I have relied in order to show that it was not merely the failure "to find other more probable examples of glittering bodies in nature" which led me to adopt the view alluded to by Mr. Sibley. Although I still consider that my hypothesis is probable, at any rate for the *Vanessidæ*, I am convinced that the resemblance to other glittering objects, such as those mentioned by Mr. Sibley, has favoured the development and especially the persistence of the metallic appearance. E. B. POULTON.

The Aryan Cradle-land.

"IT will be for the benefit of our science," said the President of the Anthropological Section of the British Association, "that speculations as to the origin and home of the Aryan family should be rife; but it will still more conduce to our eventual knowledge of this most interesting question if it be consistently borne in mind that they are but speculations." With the latter, no less than with the former opinion, I cordially agree. And as, in my address on the Aryan cradle-land, in the Anthropological Section, I stated a greater variety of grounds in support of the hypothesis of origin in the Russian steppes than has been elsewhere set forth, I trust that I may be allowed briefly to formulate these reasons, and submit them to discussion.

(1) The Aryans, on our first historical knowledge of them, are in two widely separated centres, Transoxiana and Thrace. To Transoxiana as a secondary centre of dispersion the Eastern Aryans, and to Thrace as a secondary centre of dispersion the Western Aryans, can, with more or less clear evidence, or probable inference, be traced, from about the fourteenth or perhaps fifteenth century B.C.; and the mid-region north-west of Transoxiana and north-east of Thrace—and which may be more definitely described as lying between the Caspian and the Euxine, the Ural and the Dnieper, and extending from the forty-fifth to the fiftieth parallel of latitude—suggests itself as a probable primary centre of origin and dispersion.

(2) For the second set of facts to be considered reveal earlier white races from which, if the Aryans originated in this region, they might naturally have descended as a hybrid variety. Such are the facts which connect the Finns of the north, the Khirgiz and Turkomans of the east, and the Alarodians of the south, with that non-Semitic and non-Aryan white stock which have been called by some Allophyllian, but which, borrowing a term recently introduced into geology, may, I think, be preferably termed Archaian; and the facts which make it probable that these white races have from time immemorial met and mingled in the South Russian steppes. Nor, in this connection, must the facts be neglected which make great environmental changes probable in this region at a period possibly synchronous with that of Aryan origins.

(3) In the physical conditions of the steppes characterizing the region above defined, there were, and indeed are to this day, as has been especially shown by Dr. Schrader, the conditions necessary for such pastoral tribes as their language shows that the Aryans primitively were; while, in the regions between the Dnieper and the Carpathians, and between the Oxus and the Himalayas, the Aryans would, both in their south-western and south-eastern migrations, be at once compelled and invited, by the physical conditions encountered, to pass at least partially from the pastoral into the agricultural stage.

(4) The Aryan languages present such indications of hybridity as would correspond with such racial intermixture as that supposed; and in the contemporary language of the Finnic groups Prof. de Lacouperie thinks that we may detect survivals of a former language presenting affinities with the general characteristics of Aryan speech.

(5) A fifth set of verifying facts are such links of relationship between the various Aryan languages as geographically spoken in historical times, such links of relationship as appear to postulate a common speech in that very area above indicated, and where an ancient Aryan language still survives along with primitive Aryan customs. For such a common speech would have one class of differentiations on the Asiatic, and another on the European side, caused by the diverse linguistic reactions of conquered non-Aryan tribes on primitive Aryan speech, or the dialects of it already developed in those great river-partitioned plains.

(6) A further set of verifying facts are to be found in those which lead us more and more to a theory of the derivative origin of the classic civilizations, both of the Western and of the Eastern Aryans. Just as, between the Dnieper and the Carpathians, and between the Oxus and the Himalayas, there were such conditions as must have both compelled and invited to pass from the pastoral into a partially agricultural stage; so, in passing southward from each of these regions, the Aryans would come into contact with conditions at once compelling and inviting to pass into a yet higher stage of civilization. And in support of this all the facts may be adduced which are more and more compelling scholars to acknowledge that in pre-existing Oriental civilizations the sources are to be found, not only of the Hellenic and the Italic, but of the Iranian and the Indian civilizations.

(7) Finally, if the Hellenic civilization and mythology is thus to be mainly derived from a pre-existing Oriental or "Pelasgian" civilization, it is either from such pre-existing civilizations, or from Aryans such as the Kelto-Italiots, migrating northward and southward from Pelasgian Thrace, that the civilization of Western and Northern Europe would, on this hypothesis, be traced: and a vast number of facts appear to make it more probable that the earlier civilization of Northern Europe was derived from the south than that the earlier civilization of Southern Europe was derived from the north.

The three conditions of a true solution of the problem either of Semitic or of Aryan origins appear to be these. First, the locality must be one in which such a new race could have ethnologically, and secondly philologically, arisen as a variety of the Archaian stock of white races; and thirdly, it must be such as to make easily possible the historical facts of dispersion and early civilization. And I venture to submit the above sets of facts as not inadequately, perhaps, supporting the South Russian "speculation as to the origin and home of the Aryan family." J. S. STUART GLENNIE.

The Shealing, Wimbledon Common, September 22.

Mr. Dixon's Mode of Observing the Phenomena of Earthquakes.

MR. HAROLD DIXON'S letter in NATURE of Sept. 18 (p. 491) is exceedingly interesting to seismologists. On two occasions he was able to make the only kind of observation which is of any value unless seismographs are actually employed; he has been able to make these in England, where earthquakes are rare, and I know of no record of such definite information being given by any of the trained observers in Japan, where earthquakes are so numerous. It requires great coolness to make such observations at such a time.

Seismographic records show that even in destructive Japanese earthquakes the vertical displacement of the ground is usually less than one millimetre, so that the mere *difference* in vertical displacement observed by Mr. Dixon between two points in the same room must have approached five hundred times the greatest *absolute* vertical displacement in Japan. Mr. Dixon truly says that, if the displacement observed by him had been due to the movement of the hill itself, it must have meant a good deal, for it would have meant some hundreds of thousands of times the greatest vertical earth movement recorded by any seismograph.

When I say that Mr. Dixon's letter is interesting, I make the assumption that what he observed was not merely what anybody observes who raises his head when looking at a distant hill through a window. JOHN PERRY.

31 Brunswick Square, W.C., September 24.

Butterflies Bathing.

IN NATURE of August 21 (p. 402) is a note taken from the *Victorian Naturalist* describing an observation made by Mr. G. Lyell, Jun., of Melbourne. He states that several butterflies (*Papilio macleayanus*) were seen to enter the water backwards, remain partly submerged for about half a minute, and then fly off to the hill-sides refreshed with their bath. The heat of the weather is given as the cause of their action.

I should like to suggest that the insects were probably engaged in *depositing their eggs*. Perhaps some one who has the opportunity will ascertain if the larva of this butterfly is aquatic, or feeds on plants growing at the water's edge.

G. A. FREEMAN.

St. Olave's Grammar School, Southwark.

Surface-tension and Surface-viscosity.

IF an oiled needle be placed on the surface of pure water, it will be supported, but if it be washed in a solution of potash, it will sink. In the first case the effect cannot be due to the surface-tension, which is much diminished by the oil. Has the viscosity of the oil anything to do with it? Also in the case of a soap-bubble, is the effect due to viscosity, and not to surface-tension; and what is the difference between surface-tension and surface-viscosity? They are both, no doubt, due to cohesion, but it is difficult to form definite conceptions of the two properties. Would any of your readers kindly answer the above questions, and give references to any works bearing thereon? Maxwell's "Theory of Heat," on capillarity and viscosity, does not seem to throw any light on the matter. W. P. O.

Leicester, September 25.

ON STELLAR VARIABILITY.[1]

II.

I HAVE before stated that the variability phenomena observed in stars of the Groups I. and II. and VI. are produced by the same cause; all differences in the details of the effects being due to the different physical nature of the central body. In Groups I. and II. it is a swarm of meteorites with which we have to deal; in Group VI. it is a condensed star of low radiation surrounded by a dense atmosphere containing carbon in some combination.

In both cases the bodies are normally dim; in Groups I. and II. they are so because the meteorites when undisturbed are relatively free from collisions; in Group VI. they are so for the reason stated above, the star being on the verge of extinction.

I insist upon this dimness, because the dimmer the central body the more important becomes the luminosity caused by, or set up in, secondary swarms. Further, such variability as we are now considering is unknown in the case of the hotter stars.

It is clear that phenomena produced in either group *by the action of two swarms* should strongly resemble each other, and that if it be found that this explanation holds good in one case it should be found to hold equally good in the other. It is to be expected then that phenomena observed in each may throw light upon the other, and that the view advanced may be tested by the differences observed.

Let us consider two hypothetical cases, to start with, in Groups I. and VI.

In Group I. we have a condensing nebula the light of which when undisturbed is say 6 mag. Round this there revolves a cometary swarm say in six time units. At periastron collisions occur which raise the light of the combined swarms to 3 mag. There is also another similar swarm revolving in say twelve time units. The conditions are such that this second swarm produces a smaller disturbance which only raises the light to 4½ mag. We will assume the periods to be exactly commensurable, and the apastra to occur together. It is obvious that alternate minima will be raised by this second revolving swarm, *but the maxima will be constant*.

In order to put results of this nature into diagrammatic form we must consider that we are dealing with certain

[1] Continued from p. 419.

additions of light to the constant light of the star. These additions must be shown as such.

It is very important that I should point out that for this method of direct integration to be adopted a scale of light units must be employed, *for the reason that the amount of light which is sufficient to produce a change of a magnitude in a faint star would only produce a change of a fraction of a magnitude in a brighter star.*

Taking the light of a star of magnitude m as a unit, and using the formula

$$L_{m-n} = (2 \cdot 512)^n L_m$$

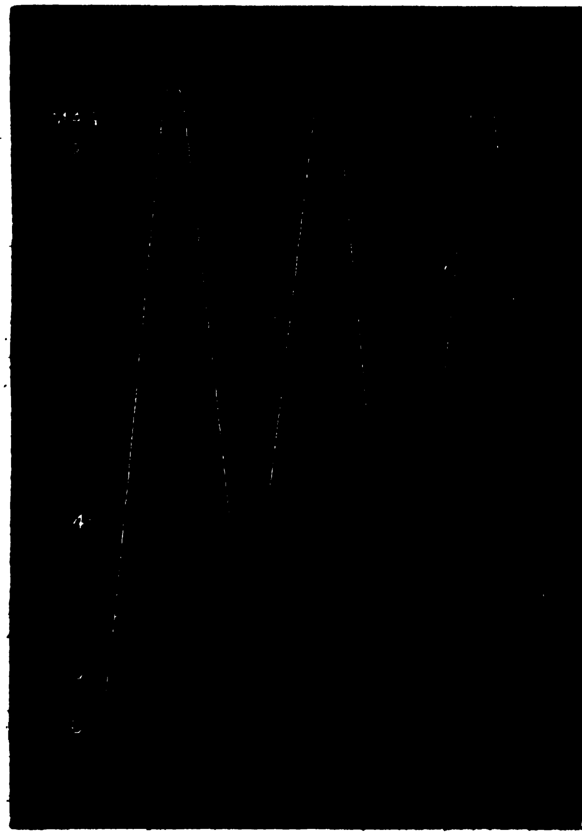
in which L_m represents the light of a star of magnitude m and L_{m-n} the light of a star n magnitudes brighter, we get—

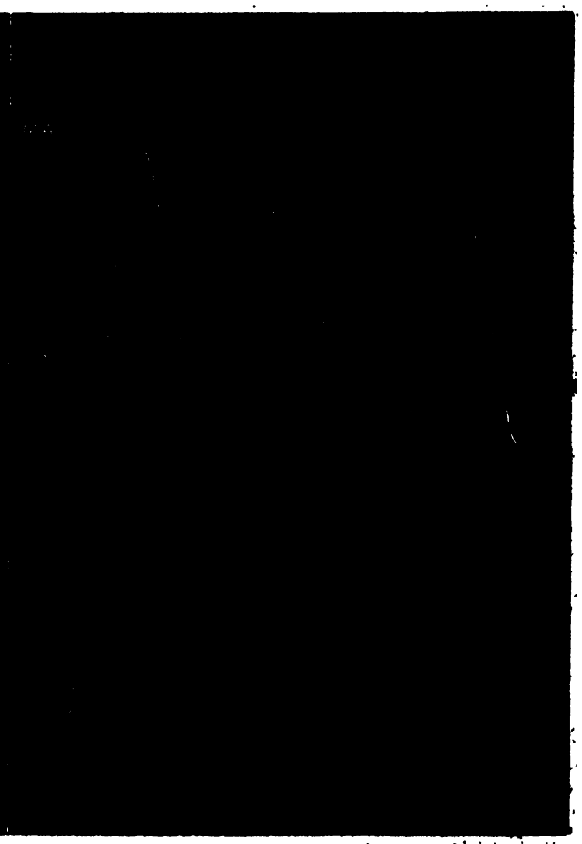
$$L_{m-1} = 2 \cdot 51\ L_m$$
$$L_{m-2} = 6 \cdot 31\ L_m$$
$$L_{m-3} = 15 \cdot 85\ L_m$$
$$L_{m-4} = 39 \cdot 78\ L_m$$
$$L_{m-5} = 100 \cdot 02\ L_m$$

The amount of light to be added for the different magnitudes will therefore be as follows :—

Additions for one magnitude $= (\ 2 \cdot 51 - 1\ )L_m = 1 \cdot 51\ L_m$
,, ,, next ,, $= (\ 6 \cdot 31 - 2 \cdot 51)L_m = 3 \cdot 80\ L_m$
,, ,, ,, ,, $= (\ 15 \cdot 85 - 6 \cdot 31)L_m = 9 \cdot 54\ L_m$
,, ,, ,, ,, $= (\ 39 \cdot 78 - 15 \cdot 85)L_m = 23 \cdot 93\ L_m$
,, ,, ,, ,, $= (100 \cdot 02 - 39 \cdot 78)L_m = 60 \cdot 24\ L_m$

It is obvious that these differences are in exactly the same proportion to each other as the numbers representing the light of the stars of different magnitudes, and if in our diagrams we take a certain length of line to represent the added light equivalent to one magnitude, about $2\frac{1}{2}$ times this will represent the added light for the next magnitude, and each succeeding magnitude will be represented by a line $2\frac{1}{2}$ times as long as the preceding one. A scale of this kind must be adopted in integrating the effects of two sources of added light, for the reason already stated.





Time-units ... 0 6 12 18 0 6 12 18

FIG. 1.—Hypothetical curve in light-units.

FIG. 2.—Hypothetical curve in magnitudes.

Thus while the amount of light to be added to a sixth magnitude star, to take an instance, to increase it to the fifth is $1\frac{1}{2}$ units, the number of the same units to be added to a fourth magnitude star to make it a third is $9\frac{1}{2}$. Hence the $1\frac{1}{2}$ units which raise a star of the 6th to the 5th magnitude—that is, one whole magnitude—would only increase a fourth magnitude star by about one-sixth of a magnitude.

To graphically represent what happens when by cometary action a star is raised three magnitudes above magnitude m, we get, in the above light-units—

1·512 additions for one magnitude
3·80 ,, ,, the next magnitude
9·54 ,, ,, ,, ,,

The sum of these numbers $= 14 \cdot 85$, represents the *added* light.

The plan on which the following curves have been drawn will be gathered from the table given below, which shows how on the above basis the light-units and magnitudes correspond :—

Magnitude step.	Light addition for: Integral part of step.	Fractional part of step.	Total light addition.
½ ...	0 ...	0·58 ...	0·58
1 ...	1·51 ...	0 ...	1·51
1½ ...	1·51 ...	1·46 ...	2·97
2 ...	5·31 ...	0 ...	5·31
2½ ...	5·31 ...	3·66 ...	8·97
3 ...	14·85 ...	0 ...	14·85
3½ ...	14·85 ...	8·61 ...	23·46
4 ...	38·78 ...	0 ...	38·78
4½ ...	38·78 ...	23·08 ...	61·86
5 ...	100·02 ...	0 ...	100·02
&c. ...	&c. ...	&c. ...	&c.

In the hypothetical case represented in Fig. 1 the constant light of the central swarm may be taken as 6 mag., and the added light of the two secondary swarms as varying from nil to 3 mag. and from nil to $4\frac{1}{2}$ mag. respectively. It is then obvious that the integrated effects of the light added produce constant maxima of 14·85 units, and minima alternately 0 and 2·97. We can in this way represent the light-curve of a star which changes its magnitude from 3 to $4\frac{1}{2}$ and 3 to 6 alternately.

The relative scales of light-units to brightnesses shown

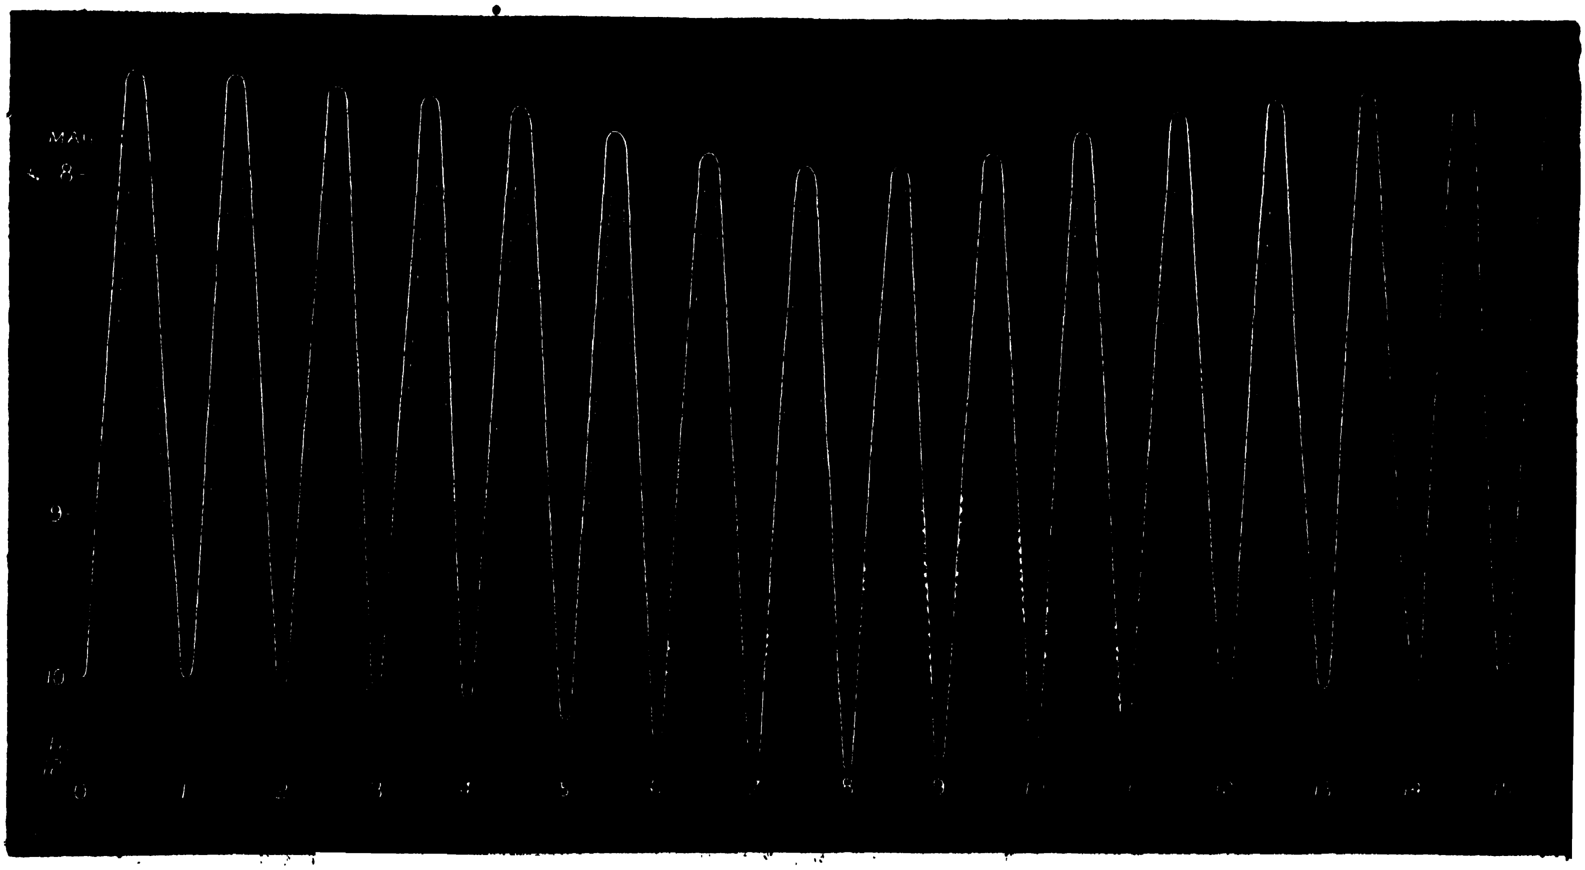


FIG. 3.—Hypothetical curve in light-units.

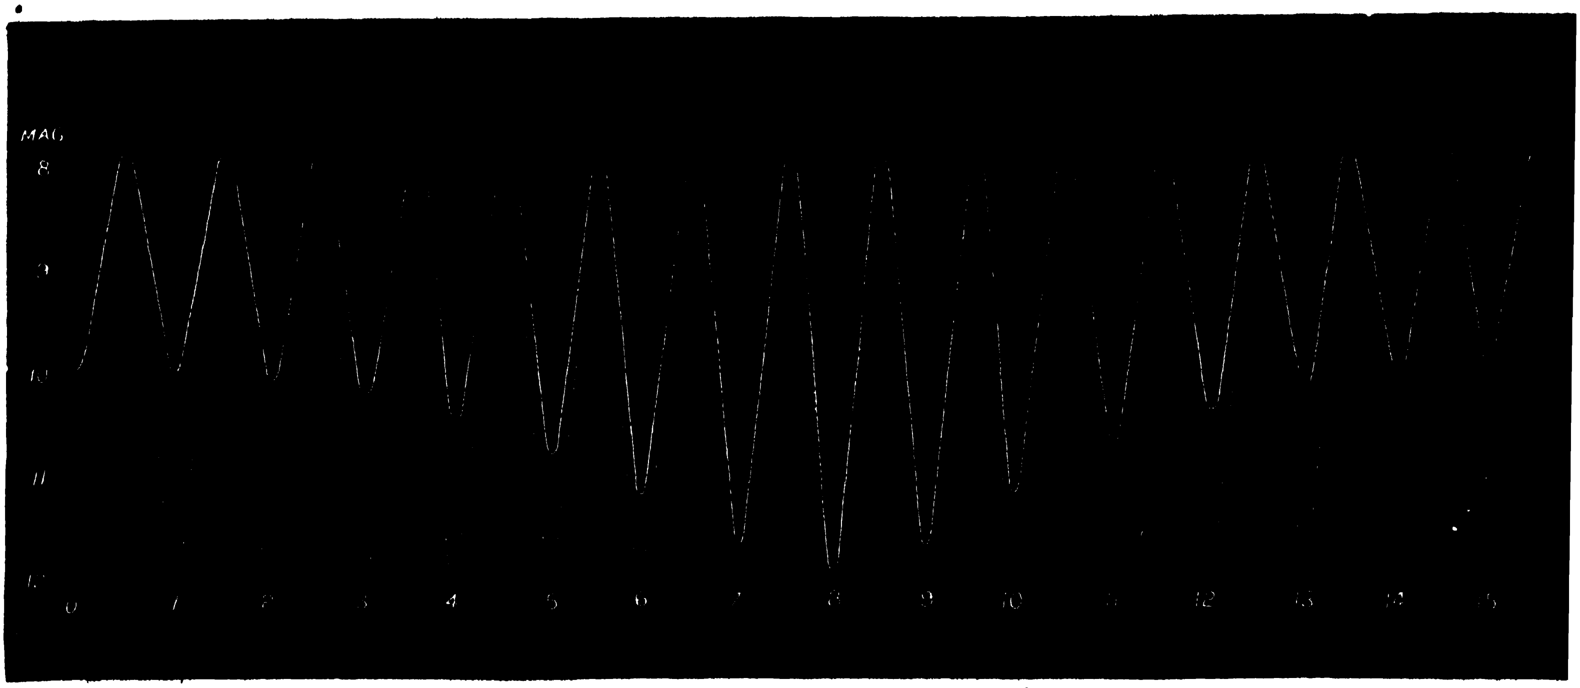

FIG. 4.—Hypothetical curve in magnitudes.

by the foregoing figures, however, enable us to transpose the diagram to one in which equal spaces represent equal differences of magnitudes. This is shown in Fig. 2.

In the diagrams, the light-curves of the two subsidiary swarms are represented by dotted lines, and the integrated result by the continuous line. One of the revolving swarms has a period of 6 units of time, and the other a period twice as long. The eccentricity of the primary swarm is such that it adds, at maximum, 14·85 light-units, while the secondary swarm adds 2·97 light-units.

A comparison of the two diagrams will make clear what

has already been said about the relative value of the light of one magnitude at the top and bottom of the curve.

We next take a hypothetical case from Group VI.

Here, instead of a nebula, dim owing to absence of collisions brought about by disturbances, we have to deal with a condensed body of small luminosity, the light of which is strongly absorbed by a carbon atmosphere.

We first consider the action of two subsidiary swarms, one producing more light with a short period, the other less light with a period say fifteen times longer. In fact we have one comet with an orbit of great eccentricity and short period, and another of small eccentricity and long period. We will assume the periastra to be coincident.

As the light is generally feeble, we may take the constant luminosity of the star as of the twelfth magnitude, and that it is raised to the eighth magnitude by the added light of the swarms at perihelion. We have then a difference of four magnitudes.

Proceeding as before we have :—

1·51	addition for one magnitude	
3·80	,,	the next
9·54	,,	,,
23·96	,,	,,

The sum of the added light gives us 38·81 of the light-units adopted = $(2{\cdot}512)^4 - 1$.

The continuous curve represents in Fig. 3 the integrated effects expressed in light-units of the two added light sources, and it will be seen that the result is a variable with both maxima and minima also periodically variable. But although both maxima and minima are variable by an equal number of light-units, the effect on magnitude is totally different. Whereas the minimum varies by two magnitudes, the maximum only varies by about one-tenth of a magnitude.

In the hypothetical case represented, the maximum varies between 7·8 and 7·9, whilst the minimum varies between 10·0 and 12.

Like the curve for the variable of Group II., this may also be transferred to one in which equal differences of magnitudes are represented by equal spaces.

This is shown in Fig. 4, and here again it will be seen that, as in the former case, in adding a change of magnitude at the bottom of the curve to the top of the curve the magnitude-change is diminished according to the ratio of light-units.

The question now arises, Are there any stars in the heavens the phenomena of which can be represented by the hypothetical curves which we have just given? If so, we shall be justified in tracing a *vera causa* in the hypothesis under consideration. It may be here stated that one of the received explanations of such a variability as is represented on our first hypothetical diagram is that due to Prof. Pickering, who conceived that the observed effect might be produced by a surface of revolution; the ratio of the axes being 5 : 3, with a dark portion at one of the ends and symmetrically situated as regards the longer axis.[1]

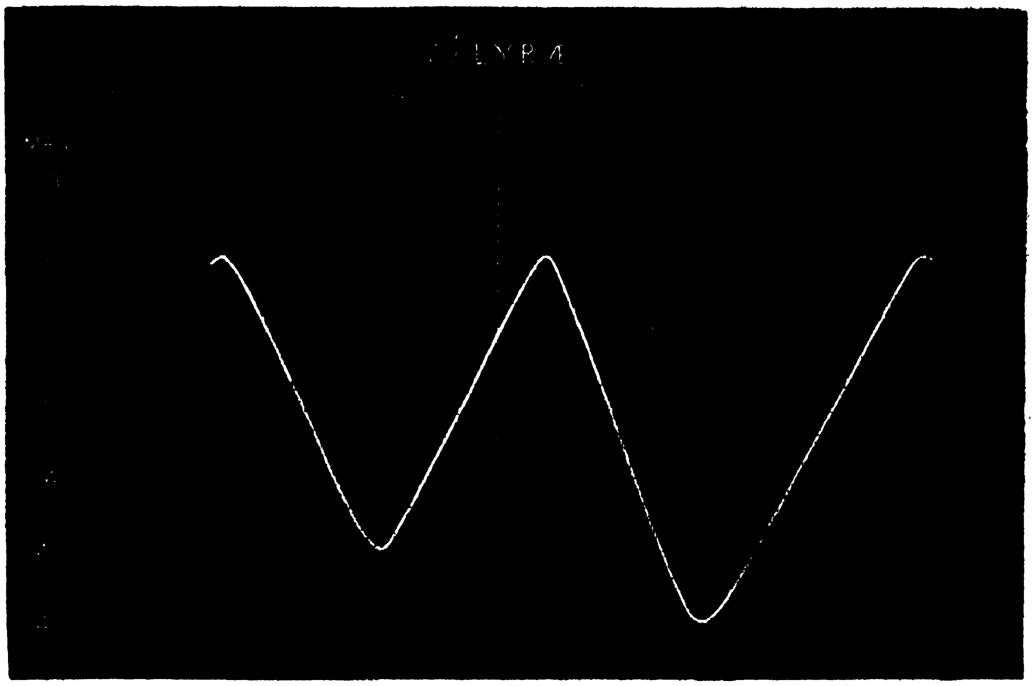

FIG. 5.—Light-curve of β Lyræ.

A reference to Fig. 5 will show that the hypothetical curve shown in Fig. 2 strikingly represents the actual light-curve of β Lyræ (actual magnitudes are not in question), and I submit therefore that the well-known phenomena of that star are produced by the causes I have suggested rather than by the complicated apparatus suggested by Prof. Pickering, to say nothing of the earlier suggestions of Maupertius and others.

I append another diagram (Fig. 6) to show that the second hypothetical curve is a close approximation to the light-curve of U Cygni, one of the best observed variables in Group VI.; and here I must express my obligations to Mr. Knott, who has freely communicated all his observations of this star to me, and has permitted me to publish them in this form.

Unfortunately, though the observations are of such a high order of exactness, they are not continuous. The parts of the curve in which the line is continuous represent the actual observations. The dotted lines added are for the purpose of enabling a comparison to be made with Figs. 3 and 4, in which the probable relations of the periods and intensities of the two hypothetic swarms are shown in light-units and magnitudes respectively.

The similarity between the hypothetic case represented and Mr. Knott's actual observations greatly strengthens my view.

It follows very clearly from the above considerations that on my hypothesis there should be frequently found rhythmical variations at the minimum, while the change at maximum is so slight that our best observers fail to notice it.

[1] Gore in "Astronomy for Amateurs," p. 238.

The smaller the range, the more will both maxima and minima be affected by the subsidiary swarms. W Cygni is a case in point.

It has been before remarked that the hypothesis demands that in sparse swarms of meteorites (Groups I. and II.) the ascent to maximum, due to the sudden action of the colliding swarms, should be much more rapid than the descent to minimum, for the reason that the descent must represent a *gradual* cooling down of the disturbance. This more rapid ascent has been noted in

R Piscium	Known Group II. stars.
S Vulpeculæ ...	
R Leonis Minoris	
R Ursæ Majoris	
R Corvi	
W Cygni	
S Cassiopeiæ ...	Group not yet determined.
R Arietis	
R Orionis	
T Delphini ...	
T Vulpeculæ ...	

I have also suggested that the short minimum is a measure of the indirect disturbance, but it is easy to imagine that this short minimum will not be invariable under all conditions, and accordingly we find in R Persei with a period of 212 days, a long minimum.

In stars of Group VI., on the other hand, where we have simply to deal with the added light of comets passing perihelion, there is no reason why this should happen, indeed, it ought to be rather the other way, since comets put on their greatest brilliancy after perihelion. As a matter of fact, so far as my inquiries have gone, I have not yet come across a case of a Group VI. star showing any great difference in the times spent in rising and falling.

On the hypothesis a *perfectly* constant period can only occur in the case of those double swarms in which the central one has a regular figure and density. The moment this condition is departed from, seeing that the central swarm is certain to be in rotation, variation of period as well as of maximum must be expected.

Nor is this the only variation which depends upon the central body. In the absence of knowledge in each case, we must assume that the structure of the central swarm resembles that of those which have been examined in Andromeda, Ursa Major, and Canes Venatici—that is, *the meteoritic density will vary locally* (S Aquilæ), and some of the observations made may be explained on the supposition that the subsidiary swarm breaks into regions in which the density is suddenly increased, as if we were noting the result of a ring being pierced (R Aurigæ).

FIG. 6.—Light-curve of U Cygni, showing Mr. Knott's actual observations.

We have only to look at Mr. Roberts's photograph of the nebula in Andromeda, and consider under what different conditions a secondary swarm might reach the same periastric distance if there were any rotation in the nebula or any movement of the nodes, to recognize the importance of taking the above points into consideration.

If there be a condition of the central body anything like that of the nebulæ named, it must be borne in mind that in the struggle for existence those swarms moving in the plane of the intakes and in the same direction, will be those that will longest survive; hence we ought to be able to explain the light-curves on the supposition that the conditions of the secondary swarms are as stated above, and it is seen that we can so explain them.

When we have more than one subsidiary swarm it is easy to see that certain relations of the regular periods of their orbital motions will produce an irregularity in the compound period; so that a rhythmic change of period will enable us to learn somewhat of the relation of the relative intensity and period of each of the swarms. We are really in presence of a *light-tide*, the elements of which can be found by analysis, as occurs with other tides nearer home.

The explanation suggested by the hypothesis of the variability of stars of Group VI. seems also to throw light upon the strange colours of some of them. R Leporis, for instance, one of the most marked variables in the group, is the famous crimson star observed by Mr. Hind. Now crimson = red + blue. All these stars are red, and in many of them the absence of the blue is one of the most emphasized characteristics of the spectrum.

But suppose that the secondary swarm which adds its light at maximum is a comet with the usual carbon bands, we shall get this condition of things:—

	Blue.	Green.	Citron.
Bands in star	masked by continuous absorption	absorbed ...	absorbed
Bands in subsidiary swarm ...	bright ...	bright ...	bright

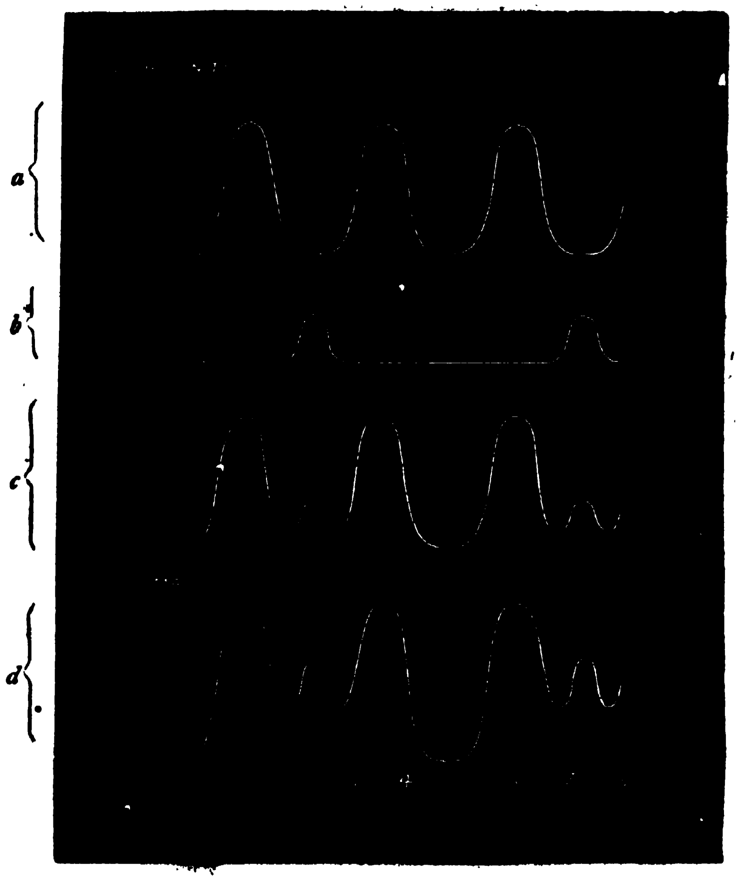

FIG. 7.—Periods 2 to 1. Apastra coincident.

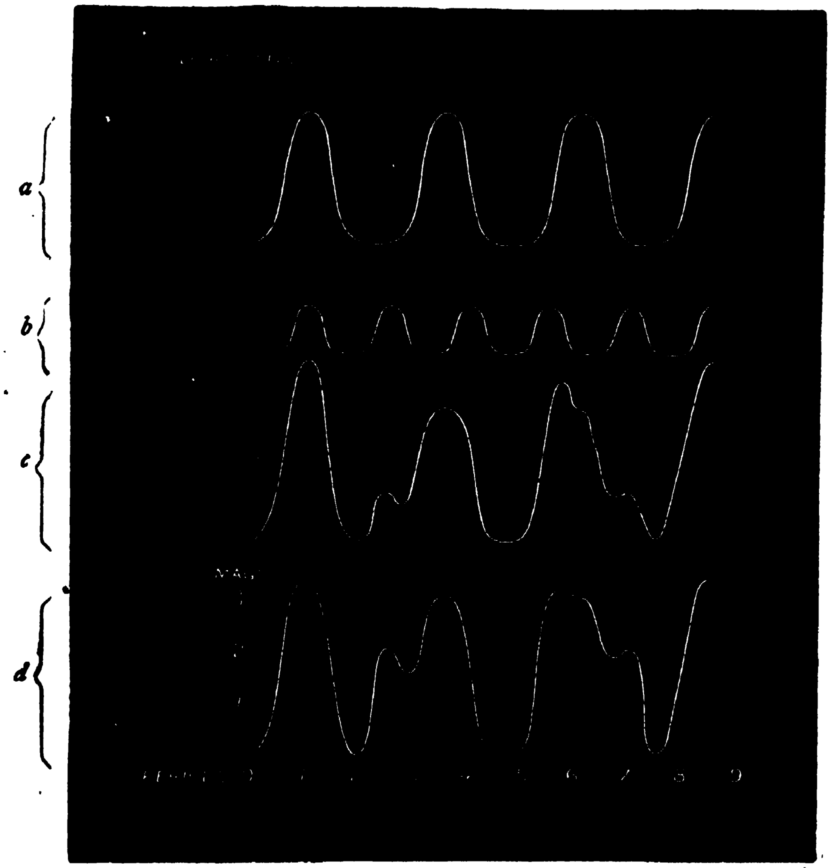

FIG. 9.—Periods 5 to 3. Periastra coincident.

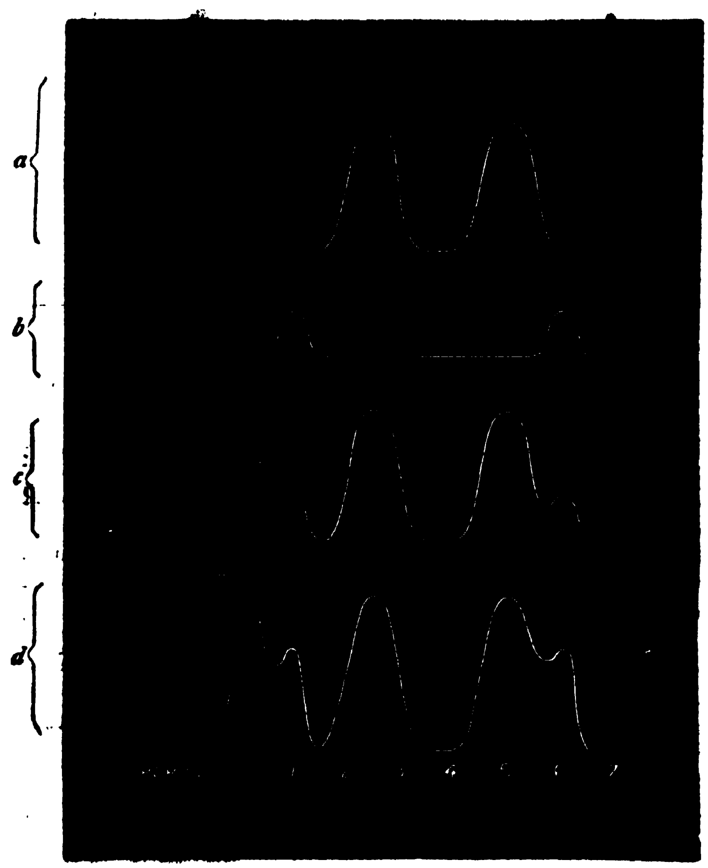

FIG. 8.—Periods 2 to 1. Apastra not coincident.

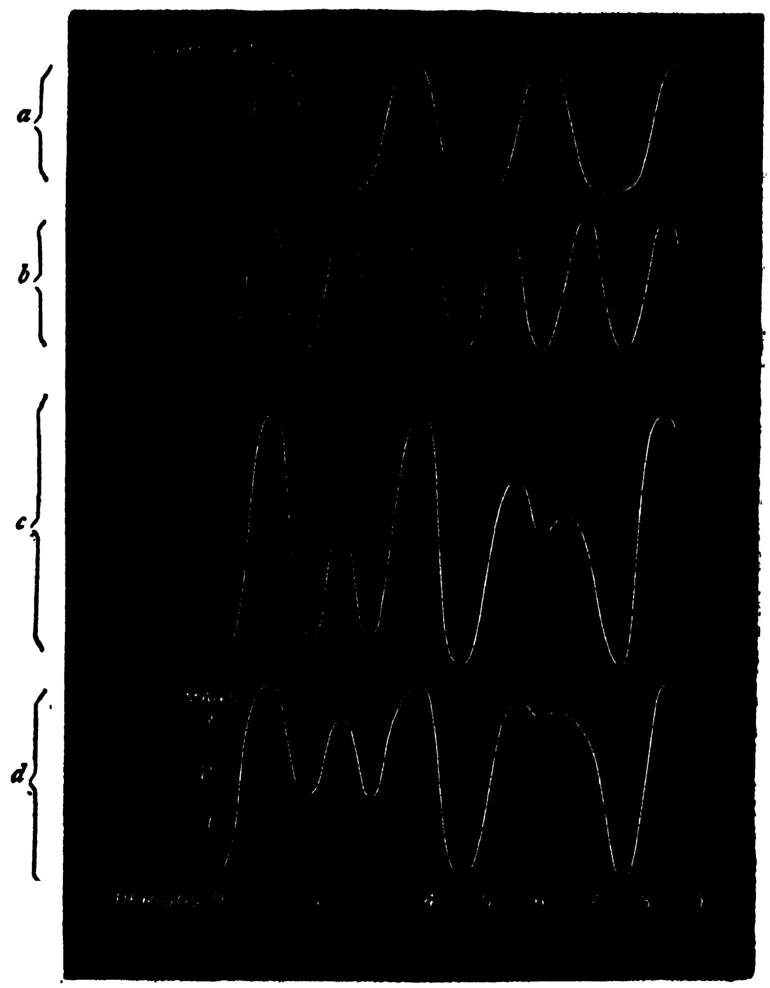

FIG. 10.—Periods 5 to 3. Periastra not coincident.

a Principal swarm. *b*. Subsidiary swarm. *c* Result in added light-units. *d*. Result in added magnitudes.

in other words, the bright fluting of carbon in the green and blue of the subsidiary swarm will just *mask* the absorption bands. They will *pale*, and the colour of the star (red) will be but slightly affected from this cause; but the blue flutings will be clear gain to the blue end of the spectrum, and crimson will result.

If this explanation be conceded, it is clear that comets travelling round such stars are conditioned very much like comets travelling round our own sun.

The general colour of the stars in Group VI. indicates that they are near the point of invisibility, the conditions being no doubt a red or white hot crust with a strongly absorbing atmosphere. It is worth while to point out that the cessation of all radiation of light from the central body need not prevent its passing on as a variable star to Group VII. As we must assume comets to be shreds of nebulæ, *i.e.* meteoritic fields or streams, filched by masses which pass near them; and as the mass remains after the light has gone, there will be the same attraction at work, and we have no right to assume that it will not act in the same way as heretofore.

We can gather from this that practically there can be no permanently dark bodies in space; they *must* at one time or another be accompanied by comets, and they must therefore be variables.

Here a most interesting point comes in: if the phenomena of the repulsion of comets' tails, or, in other words, the repulsion of carbon in some form or other from cometary swarms, depends upon the thermal energy of the central body, this result can no longer happen when the central body has cooled down. The effect of this upon the spectrum of such a compound system is well worth inquiring into.

In the hypothetical curves I have already given, I have dealt with simple cases. But in the stars there will be certain to be complex ones brought about by the successive periastra or apastra not being coincident in the two swarms (to deal only with two), and by different relationships in the periods.

I append (Figs. 7–10) some hypothetical curves worked out both in light-units and magnitudes, the conditions being stated for each. The paucity of actual light-curves available prevents any inquiry as to the stars in which the conditions here imagined actually exist, but in the absence of such knowledge it is still easy to gather that different periods separating maxima, secondary minima of unequal periods, and great variations in the rise to and fall from maximum, instead of necessarily being the result of "irregularity," are all demanded by the most perfect regularity, provided we have more than one swarm to deal with under conditions anything like those employed in the hypothetical curves above given.

If there is anything of value in what I have advanced, it is quite clear that the observations of variable stars and variable star catalogues require considerable revision. First, arrangements should be made with the observatories of America and India so that the observations of a certain number of stars in the northern hemisphere should be observed as continuously as possible. The relative brightening of the bright carbon flutings in stars of Groups I. and II., and the paling of the dark carbon flutings in Group VI., should be spectroscopically watched in each case.

It is highly important also that the precise group to which each variable belongs should be determined at once, and that this datum should take the first place in the working catalogues employed.

The observations should also be recorded when made on light-curves, the time ordinate being contracted as much as possible in order that the genesis of the compound curve may be suggested as soon as possible, so that future observations can be controlled, and the greatest attention be given at the critical periods.

The colour-observations have done their work and have had their day: less attention need now be directed to them, and much time will be liberated thereby.[1]

J. NORMAN LOCKYER.

THE LABYRINTHODONTS OF SWABIA.[2]

SWABIA, it need scarcely be said, lies to the south-east of Stuttgart—the classic ground of the Triassic Labyrinthodonts of Germany—and since it contains the same Triassic deposits, we should naturally expect to find therein the same species of this group of Amphibians. The present memoir, remarkable alike for the splendid plates with which it is illustrated, and for the care with which the specimens have been described, is devoted to making known to the scientific world the magnificent collection of Labyrinthodont remains which have been from time to time obtained from the Swabian and Würtemberg deposits, and are now preserved in the Museums at Stuttgart, Tübingen, and Munich. Of the seventeen plates with which this work is illustrated, a large proportion are folded ones of very considerable size, while all are especially noticeable for their beauty of execution. They appear to have been printed by some special process from photographs, the finely-preserved specimens of skulls standing out with wonderful clearness from a black background. Even more noteworthy than the unrivalled execution of the plates is the perfection and beauty of the specimens themselves; and we would especially direct attention to the magnificent skull of *Metopias*, represented in plates xii. and xiii. of the work before us, as being the finest Labyrinthodont specimen that has ever come under our notice.

In the introduction to his memoir, the author, after summarizing what has been previously written on the subject, glances at the chief groups into which it has been proposed to divide the Labyrinthodonts. The forms treated of in the present memoir all belong to the typical group, the Euglypta of the British Association Committee of 1874, and the Stereospondyli of Prof. von Zittel. This group has been generally characterized, among other features, by the fully ossified centra of the vertebræ; but Dr. Fraas remarks that it is very difficult to be sure of the nature of their vertebræ, and that, at least in *Mastodonsaurus*, either the caudal vertebræ, or the vertebræ of young individuals, are of that imperfectly ossified and segmented type to which the term "rhachitomous" has been applied, so that fully ossified vertebræ only occur in the trunk region of the adult. This seems to us to indicate very clearly that the pre-Triassic *Archegosauridæ*, in which the vertebræ are always "rhachitomous," can only be separated from the *Anthracosauridæ* and *Mastodonsauridæ* by characters of family value.

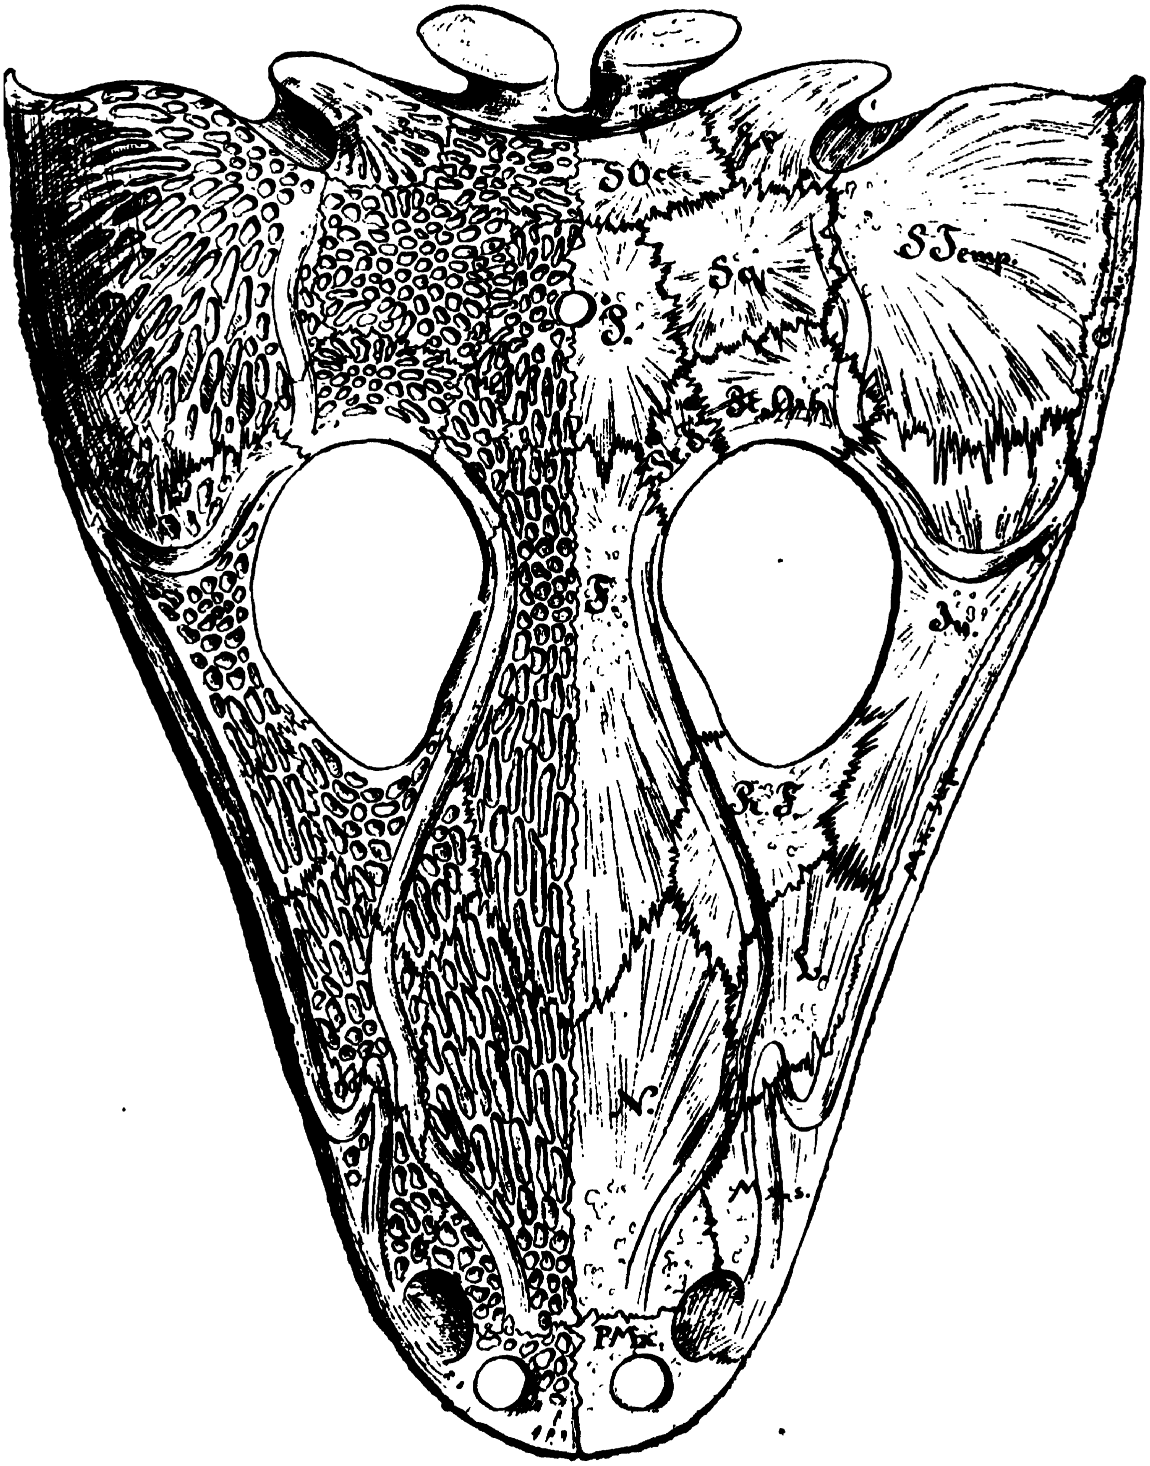
After the introductory portion, the author proceeds to discuss the geological divisions of the German Trias. Here, contrary to the views hitherto generally adopted, four main stages or groups (exclusive of the Rhætic) are recognized, viz. the Bunter-sandstein, the Muschelkalk, the Lettenkohle, and the Keuper. The separation of the Lettenkohle as a primary group distinct from the Keuper (in which it has hitherto been generally included) appears to rest on the ground that it contains many forms of Vertebrates common to the underlying Muschelkalk which do not occur in the typical Keuper. Thus the Sauropterygian genera *Nothosaurus* and *Simosaurus* range up into the Lettenkohle, but stop short of the true Keuper.

[1] I have to thank the Astronomer-Royal and Prof. A. S. Herschel for the correction of an error into which I had fallen in the part relating to light-units in the first draft of this article. The table on p. 546 I have extracted from one of the valuable letters with which Prof. Herschel has favoured me on this subject; it is fuller than the one it replaces.

[2] "Die Labyrinthodonten der schwäbischen Trias," by Eberhard Fraas. *Palæontographica*, vol. xxxvi. (1889), pp. 1–158, plates i.–xvii.

The same is true of *Mastodonsaurus giganteus*, although that form is succeeded by a closely allied species in the proper Keuper; the latter species, by the way, being not improbably the one occurring in the Bristol Rhætic, which was identified by the British Association Committee with *M. giganteus*. A table, with the names of the forms characteristic of each horizon, fully explains the author's views on all these points of geological classification.

Passing to the descriptive portion of the work, we may first of all observe that Dr. Fraas sees no reason to depart from the generally accepted homology of the bones forming the hinder part of the Labyrinthodont cranial roof; and he does not, therefore, accept the view of Dr. Baur that the bone usually termed the squamosal (*Sq.* of figure), is really the supra-temporal, and *vice versâ*; neither does he adopt the suggestion of the



Skull of *Mastodonsaurus giganteus*, one fifth natural size. *S.Occ.*, supra-occipital; *Ep.*, epiotic; *P.*, parietal; *Sq.*, squamosal; *S.Temp.*, supra-temporal; *Pt.F.*, post-frontal; *Pt.Orb.*, post-orbital; *F.*, frontal; *Pr.F.*, pre-frontal; *N.*, nasal; *P.Mx.*, pre-maxilla; *Mx. sup.*, maxilla; *L.*, lachrymal; *Ju.*, jugal; *Q.Ju.*, quadrato-jugal.

same palæontologist that the bone usually termed epiotic (*Ep.*) really represents the opisthotic of other Vertebrates. The arrangement of the Labyrinthodont cranial bones is well shown in the woodcut of the skull of *Mastodonsaurus* given on p. 44 (reproduced here), in which we notice that the squamosal has a more rhomboidal form given to it than in the restoration published by the British Association Committee in 1874.

Of the several species described, the first is the well-known *Mastodonsaurus giganteus*, of the Muschelkalk and Lettenkohle, of which the author gives a new figure of the fine skull found in the Lettenkohle of Gaildorf in 1833, and so well known in all Museums by means of plaster-casts. This magnificent specimen, we learn, has recently been thoroughly cleaned from matrix, by which means the true relations of the bones can be

more clearly seen. A woodcut of the pelvis of the same species is especially valuable, and shows (as, indeed, had been previously well displayed in Prof. Cope's figure of the pelvis of *Eryops*) that the ossified pubis is very small, and takes no part in the formation of the acetabular cavity for the head of the femur. Another species of this genus from the Muschelkalk and Lettenkohle is described as *M. granulosus*, a second from the Lettenkohle as *M. acuminatus*, and a third from the true Keuper as *M. keuperinus*.

The genus *Capitosaurus* was originally described upon the evidence of a specimen of the skull from the Keuper of Franconia, a second species being subsequently described from the equivalent beds of Würtemberg as *C. robustus*; while *C. nasutus* and *C. fronto* are smaller forms from the Bunter of Bamburg. (It may be observed, in passing, that, in the Report of the British Association Committee, all mention of these two species from the Bunter is omitted, and it is thus only suggested that the genus might possibly be represented in these beds.) Dr. Fraas describes and figures a beautifully preserved skull of *C. robustus* from Stuttgart, which exhibits the very remarkable specific peculiarity that the epiotic gives off a process to join the supra-temporal, and thus converts the auditory slit into a foramen. The author would regard this feature as of sufficient importance to form a generic character, and he accordingly proposes to separate this species from *Capitosaurus*, with the appropriate designation of *Cyclotosaurus*. We are, however, rather inclined to agree with Prof. von Zittel, who regards the feature in question merely as a well-marked specific one.

Of still more importance are the skull and skeleton of *Metopias*. Hitherto, the occipital region of the skull of this genus has been undescribed; and the magnificent skull to which allusion has already been made shows that the restoration of this part by the British Association Committee was not altogether correct. The type species of *Metopias* must have been a huge creature, only second in point of size to *Mastodonsaurus*, its skull being some 2 feet in length. In addition to the skull, the affinities of this genus are illustrated by a slab showing both surfaces of the anterior half of the skeleton. In this beautiful specimen the three plates of the thoracic buckler are preserved in their natural position, and show well-marked differences from the corresponding bones of *Mastodonsaurus*. Thus, the median plate (interclavicle), instead of ending in a sharp posterior process like the corresponding bone (entoplastral) of a turtle, is rounded; while the lateral plates (interclavicles) meet in a long suture in advance of the median plate.

In thus making accessible to the scientific world the wonderful specimens of Triassic Labyrinthodonts preserved in the Museums of Germany, Dr. Fraas has laid all students of this branch of zoology under a deep obligation to him; and his work forms a fitting companion to the volumes containing Dr. Fritsch's description and illustrations of the smaller Labyrinthodonts of the older Permian beds of Bohemia. R. L.

NOTES.

THE proceedings of the Iron and Steel Congress seem to have excited much interest in America. About four hundred members of the Iron and Steel Institute and of the German Metallurgical Association are in New York, taking part in the meetings. The sittings of the American Institute of Mining Engineers began on Monday, those of the Iron and Steel Institute on Wednesday. According to the New York correspondent of the *Times*, the foreign delegates are much pleased with the arrangements made by the Americans for their reception.

THE Harveian Oration will be delivered by Dr. Andrew, at the Royal College of Physicians, on Saturday afternoon, October 18, at four o'clock.

THE eleventh annual "fungus foray" of the Essex Field Club will be held on Friday and Saturday, October 10 and 11, in Hatfield Forest, near Great Hallingbury, a remnant of about 1000 acres of the great forest of Essex. The head-quarters for the meeting will be at Bishop's Stortford. Papers will be read, and an exhibition of fungi and other botanical specimens held, under the direction of Dr. M. C. Cooke and Mr. George Massee. Any of our readers wishing to attend, should communicate with Mr. W. Cole, Hon. Sec., Essex Field Club, Buckhurst Hill, Essex.

THE Fruiterers' Company will hold an exhibition of fruit, at the Guildhall, London, on October 6, 7, and 8. Their objects are (1) to show what excellent fruit can be grown in this country; and (2) to afford information respecting the best sorts to plant, and how to cultivate them advantageously.

AT the annual meeting of the friends of the Manchester Technical School, held on Monday, it was resolved that the property and effects of the school should be transferred to the Whitworth Institute. A letter from Mr. Chancellor Christie, one of the trustees of the late Sir Joseph Whitworth, was read. In this letter he referred to the property of the Institute, and said the trustees were prepared absolutely to give and convey their property in Peter Street, of which at present the Technical School has the use. Upon the representations made to them that it was impossible for the Technical School to be carried on for the present unless it obtained from some source a subvention of £1000 a year, or thereabouts, the legatees had undertaken to provide that sum, if necessary, for a few years, and they had already made some annual payments of this amount. As, however, the Corporation of Manchester, under the powers conferred by the recent Act, had arranged for the payment of £2000 a year to the Technical School, the amount conditionally promised by the legatees would not be required. They were willing, in lieu of this, to contribute the sum of £5000 towards the building fund. The writer added, that while he should like to see a building in every respect adequate and satisfactory, he thought it would be a mistake to contemplate the immediate erection of a building on the scale of that of which plans were prepared about a year since. "The design, indeed, should embrace everything that could be needed for many years to come, but it should be so planned that a portion only could, and should, be immediately erected, leaving the rest for the future. In fact, it would follow the lines upon which the Owens College has been partially built. An expenditure of less than £100,000 should, I think, be sufficient for all the immediate purposes of the Technical School."

WITHIN the last few days, telephonic communication has been established between London, Manchester, Liverpool, and Lancaster by the National Telephone Company, Limited. The line is not yet open for use by the public, but it was placed at the disposal of the Manchester Field Naturalists' Society on Monday evening, when a discussion on the effects of fog and town atmosphere on plant-life was held between members in Manchester and a number of corresponding members in London. Dr. Bailey, of Owens College, proposed a scheme for the chemical examination of fog, with reference to its injurious effects on animal and vegetable organisms. Colonel Mackenzie, Superintendent of Epping Forest, denied its evil effects as far as plants were concerned; Prof. R. Meldola thought that the atmosphere of London was becoming more and more harmful to plants, and that this effect was probably due to the absence of light; Mr. Philip Hartog suggested that an attempt should be made to photograph the absorption spectrum of fog, and that a *daily* analysis of the air in large towns should be made in laboratories devoted to that purpose. A sub-committee was appointed to consider the subject further.

ANOTHER determination of the atomic weight of the element beryllium has been made by Drs. Krüss and Moraht, with the purest oxide that has probably ever been prepared (*Berichte*, No. 13, 2552). The result is eminently satisfactory to those who entertain a certain amount of belief in a modified "Prout's law," for the value obtained, 9·05 when oxygen is considered 16, is almost exactly a whole number, much nearer the round number 9 than the value obtained by Nilson and Petterson, 9·11, and the still earlier one of Awdejew, 9·22. The method employed consisted in igniting under special conditions the sulphate $BeSO_4 + 4H_2O$. The advantages attending the use of this salt are that it is capable of preparation by a method detailed in a former communication in an almost absolutely pure state, and it is not hygroscopic. The powdered crystals lose two molecules of their water of crystallization at 105° C., and the remaining two molecules at 250°–260°. When heated to redness the residual anhydrous sulphate is decomposed, beryllium oxide remaining. The last traces of sulphuric acid are completely removed by ignition to bright redness in a stream of air saturated with ammonia gas. The beryllia used for the preparation of the sulphate was obtained from three distinct minerals—leucophone, beryl, and gadolinite. Sixteen separate determinations were made, about 20 grams of the sulphate being ignited in each case. The excellent agreement between the results is seen from the fact that the maximum value obtained was 9·08, and the minimum 9·03, when oxygen = 16. It appears, therefore, that in the case of beryllium the value obtained for the atomic weight approximates the more closely to the whole number 9 the purer the materials and the more perfect the method employed in the work.

WRITING to us on the subject of sonorous sand, Mr. Henry C. Hyndman asks whether Prof. H. C. Bolton is aware of an inland locality in South Africa, where it is stated the sands are sonorous. In a recent letter to the *Scotsman*, Mr. Hyndman mentioned that he had come across a paragraph in a work entitled "Twenty-five Years in an African Waggon," by Andrew A. Anderton, published in 1887, in which the author said, "Before leaving this part of the Griqualand West I should like to describe that peculiar sand formation on the west side of the Langberg mountain, which is in fact part of it. I heard from many of the Griquas and Potgielet living near it, that the lofty hills are constantly changing; that is, the sand hills, 500 and 600 feet in height, in the course of a few years subside, and other sand hills are formed where before it was level ground." And then in a footnote it is added, "I regret very much the description of this sand formation has been left out, it being the only extraordinary geological formation known in Africa, and fully describes the musical sand."

THERE is an interesting article in *Education* on the University Correspondence College (London and Cambridge) and its founder. Mr. William Briggs is the principal and founder, and the idea of teaching by correspondence first suggested itself to him while holding the appointment to a Marquis of Bute Professorship in a Scotch College. The idea soon took root, and the general method of work now adopted is as follows:—Students every week receive a scheme of work, consisting of selections from text-books, indications of important points, hints, notes on difficult portions of each subject that is under consideration. At the end of the first week, in addition to the above, a test paper is sent on the work of the preceding week, the answers to which are sent to the tutor on an arranged day. These are then examined and returned with corrections, hints, and model answers in each subject and solutions of all the difficulties. The advantage this method has over oral teaching is that all difficulties, &c., are committed to writing, and can be looked at over and over again and kept for future reference. The staff employed consists of forty tutors, whose academical careers were exceptionally brilliant, twenty-six of them having taken first places at London University examinations. The best judgment as to the work of the students may be formed from the following information:—In the Intermediate and B.A. examinations, 79 and 70 passes were obtained in one year. In the Honour and M.A. examination, 105 at the recent June examination passed, including the tenth, thirteenth, and seventeenth places in the Honour list; at Intermediate Arts, twenty took honours, one with a first and two with second places; at B.A., sixteen took honours, one being University Prizeman.

THE Durham College of Science, Newcastle-upon-Tyne, has issued its Calendar for the session 1890–91. The schedules for the A.Sc. and B.Sc. degrees have been re-modelled, and are now on the same lines as the corresponding examinations in the London and Victoria Universities. Attention may also be drawn to the fact that the list of subjects on which courses of lectures are delivered includes agricultural botany.

THE Calendar of the University College of North Wales for the year 1890–91 has been published.

WE have received the calendar of the Imperial University of Japan (Teikoku Dargaku) for the year 1889–90 (22nd–23rd year of Meiji), published by the University at Tokyo. This University is under the control of the Minister of State for Education, and depends for its revenue upon annual allowances from the Treasury of the Imperial Government. An accumulation fund, made up of tuition fees and other sources, helps to pay the current expenditure of the University when the cases are of such a nature as to demand the outlay. The whole University, consisting of offices of the University, library, colleges of law, medicine, engineering, literature, and science, the first hospital of the College of Medicine, &c., are situated in the grounds at Molofujicho, Hongo, Tokyo, known as Kaga-yashiki. The Botanical Garden Observatory and the second hospital of the Medical College are all situated within the city bounds, and the Marine Biological Station is situated at Misaki. The Calendar contains information on everything concerning the University, viz. University offices, regulations for colleges, courses of instruction, examinations, scholarships, fees, &c. The appendix gives the address delivered by President Watanabe on the occasion of the annual graduation ceremony, July 10, 1889.

M. E. DRAKE DEL CASTILLO has recently published a memoir, rewarded by the French Academy of Sciences, on the Flora of Polynesia.

A CATALOGUE of numerous works in every branch of astronomy has been issued by Felix L. Dames, Berlin, W., Taubenstrasse 47. To those who may wish to have copies of rare and standard astronomical publications at a reasonable price it will be found extremely useful.

MESSRS. G. PHILIP AND SONS, Fleet Street, have published a portable sun-dial adjustable for all latitudes and fitted with a compass. The model has been designed to illustrate simply and accurately the principle of the sun-dial. The equation of time on the 1st, 11th, and 21st of each month is given, so that civil time may be found. No table is given of magnetic variation, hence the fixing of the instrument in the magnetic instead of the geographical meridian involves a certain amount of error. The box into which the model fits is made exactly one cubic decimetre in capacity, and is intended to illustrate the decimal system of weights and measures.

THE *Engineer* of the 19th inst. contains an important article on "Railway Axles in India," due to a remarkable statement in the Indian technical press, to the effect that steel railway axles

had not given satisfaction, and that at considerable expense iron axles were to be substituted for them. Our contemporary observes that questions have, naturally enough, been asked, and publishes Sir A. M. Rendel's reply :—"I originally," he says, "recommended the use of steel for axles on the Bombay, Baroda, and Central India metre gauge, because I thought that steel was not only better than iron, but because its price was not more than half that of the class of iron suited for axles. I was further moved to do so by an opinion that, whilst steel was improving in quality, and daily taking the place of the best classes of iron, the quality of those classes of iron must deteriorate, because the price obtainable for them must diminish. In respect to the relative price of steel and iron, I was quite right; in respect to their relative suitability for axles, I have been wrong, or, at any rate, premature. *Commercial steel, when used in axles, seems subject to deterioration, which makes it very brittle after a few years' wear.* The consequence is that we must do now what we should certainly have done at first, had all the facts been then before us—I mean, we must substitute iron for steel. It being also desired that our waggon loads should be increased, it has been found necessary to increase the size of our axles, and their weight in iron is now 231 lbs., instead of 198 lbs. in steel; and their present cost is £2 6s., instead of about £1 2s. 6d. Had we originally supplied the large iron axles, capital would have been charged, for every such axle supplied, the sum of £2 6s. or thereabouts, instead of £1 2s. 6d., and I can see no reason why, because we attempted an economy in the first instance which experience has proved to be impracticable, capital should escape the larger charge now. It appears to me indisputable that the difference between the cost of the axles originally supplied and those now sent out should be charged to capital and not to revenue." The italics in this quotation are those of the *Engineer*, and the statement is a grave charge against steel, and one that the steel manufacturers will no doubt combat strongly. The *Engineer* does not tell us where these metre gauge axles have usually failed, and it is therefore difficult to find a reason for the wholesale rejection of steel as a suitable material for axles, always bearing in mind the general use of this material in this country for that purpose, with the greater mileage run with steel axles, be they crank or straight axles, over that obtainable from iron axles. It is to be hoped that the matter will be thoroughly thrashed out. The question of manufacture must not be overlooked. Steel rails occasionally fail at the ends owing to insufficient "crop" being cut off the rolled rail, *i.e.* the steel is not considered sound for about 3 feet from each end of the rail as it leaves the rolls, and is therefore usually rejected as "crop ends." If these axles are rolled ones, probably this might explain the failures, if they usually took place at the ends and not in the middles.

THE autumn series of science lectures at the Royal Victoria Hall began on Tuesday with a lecture on "Nebulæ," by Mr. J. D. McClure. The arrangements for lectures during the month of October are as follows:—October 7, "The Sun," by J. D. McClure; October 14, "Bees as Florists and Fruit Producers," by Rev. Prof. Cheshire; October 21, "The Colours of Animals and their Uses," by Dr. W. D. Halliburton; October 28, "Mountaineering," by H. G. Willink.

THE additions to the Zoological Society's Gardens during the past week include a Brown Bear (*Ursus arctos* ♂) from Russia, presented by Mr. G. W. Robinson; a Golden Eagle (*Aquila chrysaëtus* ♀) from the Rocky Mountains, Wyoming, U.S.A., presented by Mr. Percy Cooper; two Common Squirrels (*Sciurus vulgaris*), British, a Reticulated Python (*Python reticulata*) from Siam, purchased; five Viperine Snakes (*Tropidonotus viperinus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on October 2 = 22h. 46m. 16s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 4827	—	—	22 36 13	+60 42
(2) G.C. 4883	—	—	22 55 43	+29 33
(3) β Pegasi	2	Yellowish-red.	22 58 12	+27 29
(4) π Aquarii	5	Yellowish-white.	22 19 42	+ 0 49
(5) η Aquarii	4	White.	22 29 42	− 0 41
(6) α Pegasi	2	White.	22 59 18	+14 37
(7) 257 Schj.	9	Reddish-yellow.	21 51 9	+49 59

Remarks.

(1) In the spectrum of this nebula Dr. Huggins has recorded only the chief nebula line near λ 500. It is remarkable that Herschel describes it as easily resolvable, and if this be correct the nebula must be regarded as a cluster of nebulous stars. This important result is well worth checking, both by telescopic and spectroscopic observations.

(2) This nebula is described as "considerably bright; considerably large; little elongated; gradually much brighter in the middle; mottled as if with stars." The spectrum of the nebula is rather vaguely described by Dr. Huggins as follows: "The spectrum does not consist of one or two lines only; I believe it is continuous." The doubt should be removed by a more definite observation.

(3) The spectrum of this star is a very fine one of Group II. The dark bands, however, are by no means so strongly developed as they are in α Herculis or Mira, but still they are well marked, and, in addition, the spectrum abounds with lines. The relative feebleness of the bands, and the presence of so many lines, indicates that the star is well advanced in condensation, and this is further confirmed by my own observation of the comparatively feeble bright flutings of carbon. Most of the lines are identical with those seen in Aldebaran. D is partly hidden by a dark fluting, but lines in other places stand out prominently. They are not quite like those seen in the solar spectrum, and hence the spectrum of the star is one from which useful information relative to the criteria between Groups III. and V. may be derived.

(4) Prof. Pickering has found by photography that the spectrum of this star contains bright lines. Vogel, however, describes the spectrum as a well-marked one of the solar type, and makes no mention of bright lines. In my own observations of the star I found the dark lines characteristic of the spectrum of a star like the sun, but detected no bright ones. It is quite possible, therefore, that the bright lines are not always visible, and the spectrum should be examined with reference to a possible periodicity.

(5) According to the observations of Konkoly, this star has a well-marked spectrum of the solar type, but Gothard and Vogel describe it as one of Group IV. My own observations confirm those of Vogel.

(6) A star of Group IV.

(7) This faint star has a spectrum of Group VI., and Dunér states that the dark carbon band which separates the green and yellow zones is wider than he has seen it in any other star. The blue zone is scarcely perceptible. It seems as if this is a star which has cooled down until it is almost non-luminous, and the observation is important as indicating to a certain extent what the spectrum will be at the last stage of visibility. It appears that the carbon absorption intensifies until finally all the remaining light is absorbed.

A. FOWLER.

THE TELLURIC SPECTRUM.—The current number of *Comptes rendus* (September 22) contains an account of the expedition lately made to the summit of Mont Blanc by M. Janssen, for the purpose of observing the spectrum of the sun from an elevated station. Two years ago M. Janssen ascended Mont Blanc as far as the Grands-Mulets, a station having an altitude of 3050 metres. The spectroscopic observations then made showed that a diminution took place in the intensity of the groups of lines A, B, and a, due to the action of the oxygen in the atmosphere, and indicated very definitely that at the limits of our atmosphere these groups would disappear. To confirm these results it was resolved this year to repeat the observations at a greater elevation,

and after considerable difficulties the Cabane des Bosses was reached on August 18. The altitude of this station is 4400 metres. Work was commenced four days later, and precisely similar results obtained. The B group, which appears to consist of ten well-defined doubles when observed at Meudon, and was almost reduced to the last double at Grands-Mulets, had disappeared altogether.

These observations, in conjunction with those made last year between the Eiffel Tower and Meudon, those made by M. de la Baume Pluvinel at Candia during the annular eclipse of June 17, and those made in the laboratory at Meudon, definitely demonstrate the absence of oxygen from the sun, or, at least, of oxygen in the state that we know it.

M. Janssen thinks that, in the interests of astronomical and terrestrial physics and of meteorology, an Observatory should be established on the summit of Mont Blanc. The difficulties to be overcome in the erection of a station at such an elevation are great, but that they are not insurmountable is evidenced by the observations that have just been made.

ASTRONOMY AND NUMISMATICS.—Dr. A. Vercoutre, in *L'Astronomie* for September, points out how astronomical knowledge may be of service to numismatical science. It is known that on many antique medals, and notably on the coins of the Roman Republic, stars and members of the solar system figure sometimes as symbols and sometimes as heraldic allusions to the magistrate by whom the coin was struck. Thus, on a coin struck by L. Lucretius Trio, 74 B.C., the seven stars in Ursa Major are shown, and this constellation, being named Septem Triones, was evidently used as a phonetic allusion to the surname (Trio) of the magistrate. Again, on a coin struck in B.C. 43, Dr. Vercoutre noticed five stars, one of which was much larger than the others. He therefore concluded that the constellation represented on the coin was Taurus, as this was the only group of five stars known to the ancients in which one was more brilliant than the others. On this account he was enabled to attribute the coin to P. Clodius Turrinus, who apparently used the constellation Taurus or Taurinus as a phonetic signification of his surname. A coin struck by Manius Aquillus, B.C. 94, has figured upon it the first four stars in the constellation Aquila. They are shown in nearly the same relative positions occupied in reality, hence the coin contains the oldest known representation of a portion of the celestial vault. It is therefore possible that an inspection of the stars figured on old coins may be the means of ascertaining the identity of the magistrate under whom they were struck, or, knowing this and the constellation represented, they may be useful for the determination of proper motion.

GEOGRAPHICAL NOTES.

M. ANDRUSOFF, whose researches into the geological history of the Caspian Sea have been mentioned more than once in NATURE, gives now some interesting preliminary results of his exploration of the Black Sea. After having carefully studied all that was previously known about that sea and embodied it in an excellent paper (published in the last issue of the *Izvestia* of the Russian Geographical Society, vol. xxvi., 2), he induced the Hydrographical Department of the Russian Navy to send out a special gunboat for the exploration of the Black Sea, under Captain Spindler and Captain Wrangel. The sea was thus carefully explored from Odessa to Constantinople, and thence to Batum and Sebastopol. It appears that great depths are found everywhere within a short distance of the shore; and that from a depth of 200 metres the water of the Black Sea begins to contain sulphuretted hydrogen resulting from the decomposition of decaying organisms, so that no organisms either vegetable or animal, are met with at depths exceeding 200 metres. The Black Sea, he concludes, is not a sea, properly speaking, but an immense stagnant pond (reaching a maximum depth of 1200 fathoms) which is covered on the surface by the water of the Mediterranean and the rivers which flow into it. The full report of M. Andrusoff is expected soon, and is sure to be full of interest.

A TELEGRAM, dated Tashkend, September 15, gives some extracts from a letter written by M. Grombchevsky on July 20, at Sel-kilian. The expedition had at last reached Tibet from the north; but the hostility of the ruler of Keria compelled them to undertake the journey too early in the spring. On May 21, they were on the Tibet plateau, but weather was most inclement at that time. Hard frosts (20° C. below zero), terrible snow-storms, and a complete want of water—the snow in the mountains not having yet begun to thaw—compelled the expedition to return to Kashgaria without having accomplished the proposed programme of exploration. Later on, the want of money prevented them from returning to Tibet in the summer. M. Grombchevsky also adds that the ruler of Kanjut has entered into vassal relations to the Government of India, and that the fort Shahidulla-hodja is occupied by a garrison of Kashmerees, thus commanding the drainage area of the Raskem-daria and its pasture grounds. Besides, in April last, the beck of Kanjut took possession of the Pamir and Dangarym-bash forts, formerly occupied by Chinese garrisons; so that the fort Pamir, which is now practically under English influence, and the Russian fort Kara-kul are separated by but a three days' march over a territory densely peopled with Kirghizes. We may thus expect that the veil which has for so many centuries concealed those regions from science will soon be entirely lifted, and Northern Tibet will become as well known as Central Asia.

"THE AGE OF SCIENCE."

ON Friday evening last, Lord Derby, before distributing the awards of the Liverpool School of Science, delivered a clear, vigorous, and interesting address on some aspects of science. Ours, he said, would be remembered as pre-eminently the age of science. Our successors might excel us as writers, as politicians, as soldiers; they might surpass even the industrial energies of the present time, but it was not likely—it was scarcely possible—that in the region of science the twentieth century should witness advances greater than, or as great as, those of the nineteenth. The general experience of the world had been that brilliant but brief epochs of advance had been followed by long intervals of stagnation, and sometimes even of retrogression. Retrogression was not likely, but stagnation was quite possible. There was one phrase much employed when people talked on these subjects which, to his mind, contained a fallacy. He meant the common phrase of popularizing science. To popularize science was simply impossible. Anybody could cram up, with the help of an average memory and of easily acquired hand-books, a summary of what had been done in astronomy, in chemistry, or other sciences, but when that result was accomplished he would be very little nearer to any real gain which science could bring to him. It was only labour and perseverance, added to natural capacity, that could give a scientific mind. Some tincture of scientific knowledge was desirable for every educated person. The result might not be great, but the process was valuable. An entire absence of the scientific spirit was no doubt compatible with brilliant talent and high distinction. We did not find fault for a deficiency of that kind in a novelist, a poet, or a writer of light literature, but it was a deficiency notwithstanding. If asked what he meant by a scientific spirit, he thought he knew, but he must confess that it was more easily described in vague and general terms than precisely defined. He meant by it, in the first place, a habit of accuracy and exactness in matters of fact. In the next place, he meant that temper of mind which seeks for conclusions, but does not jump at them—which is equally opposed to the stupid incredulity of ignorance, refusing to accept any idea which is not familiar; to the reverential credulity which accepts as true any statement coming down from old or high authority; and to the careless indifferentism which, so long as a theory looks and sounds well, and especially if it flatters some previously existing feeling of prejudice, does not care on what foundation of reality that theory rests. That the world is governed by laws which we did not make and cannot abolish—laws which will operate whether we recognize or ignore them, and which it is our wisdom therefore to study that we may obey, and in obeying utilize them —that was what was taken to be the outcome of scientific teaching, and if anybody thought that a useless or an unimportant or unnecessary lesson he did not agree with him. Something else science, rightly understood, would teach us to know—what it is that we can hope to know and to understand; and to recognize how little that is, and how much lies, and probably always will lie, beyond the reach of our faculties. One word only he would add—that, having known men of many professions, he should say, as far as his observation went, the happiest lives were those which had been devoted to science. "Every step," said Lord

Derby, "is interesting, and the success of those who do succeed is lasting. What general, what orator, what statesman, what man of letters can hope to leave a memory like that of Darwin? An invalid in health, a man who seldom stirred from home, a man until his later years very little known to the outer world, but who, from his quiet study, revolutionized the thought of Europe, and will be remembered as long as Newton and Bacon. If fame be ever worth working for—I do not say it is—that kind of fame is surely, of all, the most durable and the most desirable. Well, I have perhaps digressed from our proper subject, for it is not likely that we have a future Darwin in this room, but it is no exaggeration to say that, as a rule, no man who has taken to science as the work of his life regrets the choice, while men who have done important work in other lines feel like Renan, who, at the height of his literary eminence, tells us in his autobiography that he has often regretted that science, rather than historical research, had not been the object of his early pursuit."

MIMICRY.[1]

THE relationship of mimicry to other animal colours can only be explained by giving a short account of the latter.

I. The commonest use of colour is for concealment (*cryptic*), enabling an animal (1) to escape its enemies, or (2) to approach its prey. In these (1) protective (*procryptic*) or (2) aggressive (*anticryptic*) resemblances, animals seek concealment by a likeness to some object which is of no interest to enemies or prey respectively. Similar effects may be produced by the use of foreign objects with which the animal covers itself to a greater or lesser extent (*allocryptic*).

EXAMPLES.—(1) *Procryptic Colours.* A green pipe-fish (*Siphonostoma typhle*) conspicuous in the water, but well concealed among the leaves of *Zostera:* the brown lappet moth (*Gastropacha quercifolia*), conspicuous on a smooth deal board, but well concealed among dead leaves.

(2) *Anticryptic Colours.* A large frog (*Ceratophrys cornuta*) from tropical South America, which almost buries itself in a hole in the ground, while the head, which is exposed, harmonizes with the surroundings. In this position it waits till the small animals on which it feeds approach or even walk over it.

(3) *Allocryptic Colours.* A small English crab (*Stenorhynchus phalangium*) which decks itself with pieces of seaweed: another small English crab (*Hyas coarctatus*) was shown with and without its covering of pieces of seaweed (*Ulva*, &c.).

Mimicry is closely related to the colours illustrated above, but differs in that the animal resembles an object which positively repels its enemies or positively attracts its prey rather than one which is of no interest to either. It is better, therefore, to defer its consideration until after the description of the colours which form the models for mimicry.

II. The second great use of colour is to act as a warning or signal (*sematic colour*), repelling enemies by the indication of some unpleasant or dangerous quality (*aposematic* or *warning colours*), or signalling to other individuals of the same species, and thus assisting them to escape from danger (*episematic* or *recognition colours*). In a very interesting group of cases (*allosematic*), the animal warns off its enemies by associating with itself some other animal with unpleasant qualities and warning colours.

EXAMPLES.—(1) *Aposematic Colours.* The two unpalatable English moths (*Spilosoma urticæ* and *S. mendica*, female), when disturbed, assume attitudes which serve to display their conspicuous yellow and black colours. Portchinski has recently shown that an unpalatable European chrysalis (*Limenitis populi*) bears the most detailed resemblance to a chrysalis which has been pecked and rejected by a bird. The American skunks (*Mephitis mephitica*, *Conepatus mapurito*, &c.) possess the power of emitting an intolerable stench, and are extremely conspicuous black and white mammals.

(2) *Episematic Colours.* In the common rabbit the white tail serves as a beacon to other individuals, pointing the way to the burrow.

(3) *Allosematic Colours.* A hermit crab (*Pagurus bernhardus*) is commonly found with a sea anemone (*Sagartia parasitica*) attached to its shell; in another hermit crab (*Pagurus prideauxii*) the association is more constant, and the sea anemone (*Adamsia palliata*) is specialized for life on the shell of the crustacean. Two crabs (*Polydectus cupulifer* and *Melia tessellata*), described by Möbius in some of the islands round Madagascar, invariably held a sea anemone in each claw. Two other groups of animals, sponges, and ascidians, in addition to sea anemones, are avoided by the enemies of the Crustacea, and these are also made use of by the latter. Thus the hermit crab (*Pagurus cuanensis*) is found in shells which are covered with a (generally) brightly-coloured sponge (*Suberites domuncula*): Möbius also describes a hermit crab (*Ascidiophilus caphyræformis*) which lives in a case formed by an ascidian.

III. Mimicry may be defined as false warning or signalling colours (*pseudosematic*), repelling enemies by the deceptive suggestion of some unpleasant or dangerous quality (*pseudaposematic*), or attracting prey by the deceptive appearance of something attractive to them (*pseudepisematic*). Even foreign objects commonly associated with some well-defended and aggressive species may be mimicked by a comparatively defenceless form (*pseudallosematic*).

EXAMPLES.—(1) *Pseudaposematic Colours.* The various degrees of complexity with which protective mimicry occurs in insects was shown by examples of Indian and African Lepidoptera.

(*a*) Both sexes of the Indian *Papilio agestor* closely resemble the much commoner and nauseous butterfly *Euplœa tytia.*

(*b*) An Indian moth (*Epicopeia philenora*) similarly mimics an unpalatable butterfly (*Papilio protenor*), but in this case the male moth mimics the appearance of the male butterfly, and the female moth that of the female.

(*c*) If the mimicking species became common relatively to the mimicked, the deception would be liable to be detected. We therefore find that two or more models are often mimicked by the same species. Thus the male of the Indian *Elymnias leucocyma* mimics *Euplœa binotata*, while the female mimics the female of *Euplœa linnæi.* Both these Euplœas are also imperfectly mimicked by day-flying moths (*Amesia midama*). So also the male of the Indian *Papilio castor* mimics *Papilio chaon*, while the female mimics *Euplœa core:* in the south, *Papilio chaon* is absent, and BOTH sexes of the species (*Papilio dravidarum*) which represents *P. castor*, mimic *E. core.*

(*d*) Female butterflies are exposed to more dangers than the swiftly-flying males, and we find many instances in which the former are mimetic, although the latter are not. Thus the female of *Hypolimnas bolina* mimics *Euplœa core*, while the male is non-mimetic. The same is true of *Hypolimnas misippus*, the female of which mimics *Danais chrysippus.* Two forms closely allied to the latter (some regard them as merely varieties) are also mimicked by the former.

(*e*) The mimetic females also often resemble two or more different species of nauseous butterflies. Thus the female of *Papilio pammon* appears in two forms, mimicking respectively *Papilio hector* and *P. aristolochæ;* while the females of *Euripus halitherses* (the male of which is probably mimetic) mimic *Euplœa rhadamanthus* and *Euplœa deione.*

(*f*) There are also striking examples in which the non-mimetic ancestor of a mimetic species has been preserved, *e.g.* in an adjacent island. Thus the female of *Elymnias undularis* mimics *Danais genutia* in Sikkim and North-East India; in Rangoon and Burmah there is a variety of the latter with white hind wings which is as common as the typical form, and the female of *E. undularis* is beginning to mimic this variety; in South India *E. undularis* is represented by *E. caudata*, in which the male is also beginning to mimic *D. genutia*, and the female is a more perfect mimic than in the other localities; in the Andaman Islands *E. cottonis* represents *E. undularis*, and both sexes appear to be non-mimetic, while *D. genutia* has never been recorded from this locality. A still more wonderful example is found in Africa and adjacent islands. *Papilio meriones* of Madagascar is non-mimetic, and the sexes are alike; the same is true of a closely-allied species, *P. humbloti*, recently discovered in Grand Comoro, and of *P. antinorii* recently found in Abyssinia. A very nearly related species in West Africa has a closely similar non-mimetic male, while two forms of female mimic *Danais chrysippus* and *Danais niavius.* In South Africa *Papilio cenea* has an almost identical male, while the females mimic *D. chrysippus*, the southern form of *D. niavius*, and two varieties of *D. echeria.*

(*g*) There are also examples which show us the origin of mimicry, in which the resemblance is very imperfect, but, nevertheless, sufficient to afford protection. The blue Euplœas of

[1] Abstract of Lecture delivered by Edward B. Poulton, F.R.S., on Friday, September 5, at the Leeds meeting of the British Association.

India, &c. (such as *E. harrisi*, *E. linnæi*, *E. splendens*, and *E. irawada*) form a very characteristic group, while their general type of appearance is imperfectly mimicked by a group of day-flying moths (*Amesia midama*, *A. aliris*, *A. sanguiflua*). It is extremely probable that the wonderfully close likeness of many mimetic species arose by gradual stages from some general resemblance to a type of colour or pattern possessed by some large group of unpalatable insects.

The above-cited examples are some of them well-known, they were chosen to illustrate the various different ways in which mimicry occurs.

Evidence for the evolution of mimetic resemblance has also been forthcoming as the result of recent and hitherto unpublished work.

Many moths have lost the scales which are characteristic of the order of insects to which they belong, so that their wings become transparent, and they mimic stinging insects such as wasps or hornets. This is the case with two British hawk-moths (*Hemaris fuciformis* and *bombyliformis*). It is known that when these moths emerge from the chrysalis, the transparent parts of their wings are thinly covered with scales which are shaken off during the first flight. The loss of the scales has now been shown to be due to the rudimentary nature of the stalk at the base of the scale and of the socket in which the stalk is inserted; a closely-allied Indian moth (*Hemaris hylas*) was still more completely denuded of scales, but in it also the rudimentary sockets were found to be thinly scattered over the transparent part of the wing. These facts suggested that all moths with transparent wings may be found to repeat, in the course of their own individual lives, the history of the change by which the transparency has been attained by the species. Investigation has supported this suggestion. The examination of two British moths which resemble hornets or wasps was especially instructive. In one of these (*Sesia apiformis*) the mimicry is not so perfect as in the other, and is therefore presumably of more recent date; in this moth the rudimentary scales which fall off are comparatively perfect, while in the other species (*S. bembeciformis*) they are far more degenerate, inasmuch as they have been useless to the species for a far longer period of time. It is interesting to note that these degenerate scales have not been reduced in size in either species, but are, on the contrary, much larger than the scales which are retained for the whole life of the moth. In the allied "clearwings" of the genus *Trochilium*, the transparency of the fore wing has been attained by the transparency of scales which are retained as well as by the loss of scales.

(2) *Pseudepisematic Colours.* This division not only includes the examples of aggressive mimicry in which an animal resembles another, and so is enabled to approach and injure it in some way, but also the cases of alluring colouring in which an animal possesses a lure which is attractive to its prey.

Examples of the former are seen in the flies of the genus *Volucella*, which are enabled to lay their eggs in the nests of humble-bees, &c., because of their close resemblance to the latter. The larvæ of the fly feed upon those of the bee.

Examples of alluring colouring. An Asiatic lizard (*Phrynocephalus mystaceus*) possesses pink flower-like structures at the corners of its mouth, it is probable that flies, &c., are thus allured. A terrapin (*Macroclemmys Temminckii*) from the Southern States of America, when hungry, opens its mouth and moves about two filaments at the anterior end of its tongue. These look like worms moving in a crevice in the rocks, and attract prey. The animal is otherwise perfectly motionless, and resembles a weed-covered rock. The fish *Lophius piscatorius* (the angler or fishing-frog) attracts its prey by a brightly coloured lure placed over its large mouth, the rest of the body being concealed. Certain deep-sea fishes allied to *Lophius* (*Ceratias bispinosus*, *C. uranoscopus*, &c.) have a phosphorescent lure which attracts the other fish on which they feed.

(3) *Pseudallosematic Colours.* A very striking instance was discovered by Mr. W. L. Sclater in tropical South America. The well-defended and abundant leaf-carrying ants (*Œcodoma*) are mimicked by an immature Homopterous insect possessing a shape and colour which closely resemble the ant together with the piece of leaf it is carrying.

IV. *Epigamic colours* are the bright tints and patterns displayed during courtship. As in other classes of colours the same effects may be produced by the use of foreign objects (*Allepigamic*). Examples are found in the various beautiful or curious objects collected by bower-birds for the decoration of their bowers. Especially interesting in this respect is the *Amblyornis inornata* of New Guinea.

Mutual relationship of the above-mentioned classes of colours. It is clear that I. (*Cryptic*) and III. (*Pseudosematic*) colours are closely related; they may be conveniently grouped under one head:—*Apatetic* or deceitful colours. The following scheme will be found to represent the mutual relationships:—

<table>
<tr><td colspan="2">I. Apatetic Colours.
(Resembling the environment, or some other species, or acting as a lure.)</td><td rowspan="2">II. Sematic Colours.
(Warning and Signalling.)</td><td rowspan="4">III. Epigamic Colours.
(Displayed in Courtship.)</td></tr>
<tr><td>A. Cryptic Colours.
(Protective and Aggressive Resemblances.)</td><td>B. Pseudosematic Colours.
(False Warning and Signalling Colours.)</td></tr>
<tr><td>(1) Procryptic Colours.
(Protective Resemblances.)</td><td>(1) Pseudaposematic Colours.
(Protective Mimicry.)</td><td>(1) Aposematic Colours.
(Warning Colours.)</td></tr>
<tr><td>(2) Anticryptic Colours.
(Aggressive Resemblances.)</td><td>(2) Pseudepisematic Colours.
(Aggressive Mimicry and Alluring Colouring.)</td><td>(2) Episematic Colours.
(Recognition Markings.)</td></tr>
<tr><td>Allocryptic Colours.
(Concealment gained by use of foreign objects.)</td><td>Pseudallosematic Colours.
(Resemblance to some foreign object associated with mimicked species.)</td><td>Allosematic Colours.
(Warning Colours of another Animal made use of.)</td><td>Allepigamic Colours.
(Display of foreign objects in Courtship.)</td></tr>
</table>

* The comparatively new terms employed in the lecture were due to the kind help of Mr. Arthur Sidgwick. The beautifully painted lantern slides were due to the great skill and patience of the artist, Mr. H. M. J. Underhill. The examples of *Allocryptic* and many of those of *Cryptic* and of *Allosematic* colours were painted from the living animals in the Marine Biological Laboratory at Plymouth. Colonel Swinhoe had very kindly suggested good examples of mimicry among Indian butterflies, and had lent from his beautiful collection the specimens for copying. Mr. H. Grose-Smith had kindly lent the African examples. Rev. F. J. Smith had most kindly helped in photographing the examples selected. Mr. W. R. Morfill had kindly translated Portchinski's Russian paper, thus rendering possible the use of some very interesting examples.

FORTHCOMING SCIENTIFIC BOOKS.

MESSRS. LONGMANS AND CO. announce the following:—"The Principles of Chemistry," by D. Mendeléeff, translated by George Kamensky, of the Imperial Mint, St. Petersburg, and edited by A. J. Greenaway; "Text-Book of Chemical Physiology," by Dr. W. D. Halliburton; "Human Physiology," being the substance of lectures delivered at the St. Mary's Hospital Medical School from 1885 to 1890, by Dr. Augustus D. Waller; "Elements of Materia Medica and Therapeutics," by C. E. Armand Semple, illustrated; "Notes on Building Construction," arranged to meet the requirements of the Syllabus of the Science and Art Department of the Committee of Council on Education, South Kensington—Part IV. "Calculations for Structures," illustrated; "Preliminary Survey, including Elementary Astronomy, Route Surveying, Tacheometry, Curve-ranging, Graphic Mensuration, Estimates, Hydrography, and Instruments," by Theodore Graham Gribble, illustrated; "Optical Projection: a Treatise on the Use of the Lantern in Exhibition and Scientific Demonstration," by Lewis Wright.

Among the scientific works promised by Messrs. Macmillan and Co. are the following:—Dr. Lauder Brunton's Croonian Lectures, "On the Connexion between Chemical Constitution and Physiological Action, being an Introduction to Modern Therapeutics"; "A Manual of Public Health," by A. Wynter Blyth; "Dictionary of Political Economy," edited by R. H. Inglis Palgrave, F.R.S.; "The Scope and Method of Political Economy," by I. N. Keynes, second edition; "Outlines of Psychology," by Dr. Harald Höffding, translated by M. G. Lowndes; "The Meteoritic Hypothesis," by J. Norman Lockyer, F.R.S., illustrated; "Electricity and Magnetism," a popular treatise, by Amédée Guillemin, translated and edited, with additions and notes, by Prof. S. P. Thompson, illustrated; "Popular Lectures and Addresses," by Sir William Thomson—Vol. III. "Papers on Navigation"; "Are the Effects of Use and Disuse Inherited?" by W. Platt Ball (Nature Series); new editions of Dr. Russel Wallace's "Contributions to the Theory of Natural Selection: and Tropical Nature and other Essays," and "The Malay Archipelago: the Land of the Orang Utan and the Bird of Paradise"; "The Myology of the Raven (*Corvus corax sinuatus*): a Guide to the Study of the Muscular System in Birds," by R. W. Shufeldt, illustrated; "Text-book of Comparative Anatomy," by Dr. Arnold Lang, translated by Henry M. Bernard and Matilda Bernard, with preface by Prof. Ernst Haeckel, two volumes, illustrated; "Lessons in Elementary Biology," by T. Jeffrey Parker, illustrated; "A Text-book of Physiology," by Prof. Michael Foster—Part III. "The Central Nervous System and its Instruments"; a new edition of "The Chemistry of the Hydrocarbons and their Derivatives, or Organic Chemistry," Vol. III. Part III., by Sir H. E. Roscoe and Prof. C. Schorlemmer; "The History of Chemistry," by Prof. Ernst von Meyer, translated by George McGowan; "Elements of Physics for Public Schools," by C. Fessenden; "Sound, Light, and Heat: an Elementary Text-book," by D. E. Jones, illustrated; "Elementary Applied Mechanics," by James H. Cotterill and J. H. Slade; a new edition of Todhunter's "Plane Trigonometry," revised by R. W. Hogg; "The Geometry of Position," by R. H. Graham, C.E., illustrated; "Manual of Logarithms," by G. F. Matthews; a new edition of "Class-book of Geology," by Archibald Geikie, F.R.S.; two volumes of "Macmillan's Geographical Series," edited by Archibald Geikie—"A Geography of Europe," by James Sime, and "Maps and Map Drawing," by William A. Elderton; and a "Physical and Political School Atlas," by J. G. Bartholomew.

The Clarendon Press announce "Mathematical Papers of the late Henry J. S. Smith, Savilian Professor of Geometry in the University of Oxford," with portrait and memoir, in two volumes; "A Treatise on Electricity and Magnetism," by J. Clerk Maxwell, new edition; "An Introduction to the Mathematics of Electricity," by W. T. A. Emtage; "A Manual of Crystallography," by M. H. N. Story-Maskelyne; "Translations of Foreign Biological Memoirs"—III. "Contributions to the History of the Physiology of the Nervous System," by Prof. Conrad Eckhard, translated by Miss Edith Prance, and a translation of Prof. Van't Hoff's "Dix Années dans l'Histoire d'une Théorie," by J. E. Marsh; and Count H. von Solms-Laubach's "Introduction to Fossil Botany," translated by the Rev. H. E. F. Garnsey, and edited by I. Bayley Balfour, F.R.S.

The Pitt Press announce "The Collected Mathematical Papers of Arthur Cayley, F.R.S.," Vol. III.; "Mathematical and Physical Papers," by Sir W. Thomson, Vol. III.; "A Treatise on Plane Trigonometry," by E. W. Hobson; "A Treatise on Analytical Statics," by E. J. Routh, F.R.S.; "A Treatise on Statics and Dynamics for Schools," by S. L. Loney; and two volumes of the "Pitt Press Mathematical Series"—"The Elements of Geometry after Euclid, Books III. and IV.," edited by H. M. Taylor, and "Elementary Algebra, with Answers to the Examples," edited by W. W. Rouse Ball.

Messrs. Smith, Elder, and Co. have in preparation a new work by Prof. Ferrier, being "The Croonian Lectures on Cerebral Localization," delivered before the Royal College of Physicians, June 1890.

Messrs. Sampson Low, Marston, and Co. announce "The Structure of Fibres, Yarns, and Fabrics: a Practical Treatise for the Use of all Persons employed in the Manufacture of Textile Fabrics," by E. A. Posselt, illustrated; and "Directory of Technical Literature: a Classified Catalogue of all Books, Annuals, and Journals published in England, America, France, and Germany, including their Relations to Legislation, Hygiene, and Daily Life," by Fritz von Szczepanski.

Messrs. Bell and Sons announce a revised edition of Deighton's "Euclid," Books I. and II., and Books I. to III.; "The Elements of Trigonometry," by J. M. Dyer and the Rev. R. H. Whitcombe, assistant masters of Eton College; "Solutions to the Problems in Dr. Besant's Elementary Hydrostatics"; a Key to "Examination Papers in Trigonometry," by G. H. Ward; "Colour in Woven Design," by Roberts Beaumont; and "Structural Mechanics," by R. M. Parkinson.

Messrs. Philip and Son will issue "Commercial Geography," a series of lectures by J. Scott Keltie, Librarian of the Royal Geographical Society, with numerous coloured maps and diagrams; "Across East African Glaciers, being an Account of the First Ascent of Mount Kilima Njaro," by Dr. Hans Meyer; "The Development of Africa," by A. Silva White, Secretary of the Scottish Geographical Society, illustrated with a set of 14 maps, specially designed by E. G. Ravenstein; "Magellan and the Pacific," by Dr. F. H. H. Guillemard, illustrated, forming Vol. IV. of the "World's Great Explorers and Explorations"; "Home Life on an Ostrich Farm," by Mrs. Annie Martin, illustrated; "The Unknown Horn of Africa, an Exploration from Berbera to the Leopard River," by the late F. L. James, illustrated, new and cheap edition, containing the narrative portion and notes only.

Mr. Fisher Unwin will publish a book on "Gypsy Sorcery and Fortune Telling," by Charles Godfrey Leland, illustrated; a second edition of Mrs. Brightwen's "Wild Nature Won by Kindness," with additional matter; and "Everyday Miracles," by Bedford Pollard, a work designed to present the wonders of science to young readers.

"Methuen's Science Series," edited by Mr. R. Elliot Steel, will include, among other volumes, "The World of Science," "Elementary Light and Sound," "Elementary Electricity and Magnetism," and "Elementary Heat."

Messrs. Charles Griffin and Co. will issue Dr. A. E. Garrod's "Treatise on Rheumatism and Rheumatoid Arthritis"; Dr. A. E. Sansom's "The Diagnosis of Diseases of the Heart"; "Foods and Dietaries: a Manual of Clinical Dietetics," by Dr. R. W. Burnet; "Railway Injuries: with Special Reference to those of the Back and Nervous System," by H. W. Page; "Outlines of Practical Histology," by Prof. W. Stirling, and a second and rewritten edition of "Outlines of Practical Physiology," by the same author; a laboratory course on "Pharmacy and Materia Medica," by W. Elborne; "Scientific Amusements," a variety of experiments illustrating some of the chief physical and chemical properties of surrounding objects, and the effect upon them of light and heat, by Dr. C. R. Alder Wright, F.R.S.; Prof. Roberts-Austen's "Introduction to the Study of Metallurgy"; Dr. C. Le Neve Foster's "A Text-book of Ore and Stone-Mining"; "A Text-book of Coal-Mining," by H. W. Hughes; "Aids in Practical Geology, with a Section on Palæontology," by G. A. J. Cole; "A Text-book of Electro-Metallurgy," by W. G. Macmillan; "The Design of Structures: a Practical Treatise on the Building of Bridges, Roofs, &c.," by S. Anglin; "A Zoological Pocket-book; or, Synopsis of Animal Classification," by Dr. Selenka and J. R. A. Davis; the complete volume of Prof. Jamieson's elementary manual of "Magnetism and Electricity"; a thoroughly revised edition of "Seaton's Manual of Marine

Engineering"; "Sewage Disposal Works; the Construction of Works for the Prevention of Pollution of Rivers and Estuaries," by W. Santo Crimp; and the eighth annual issue of the "Year-Book of Learned and Scientific Societies."

Messrs. Cassell promise "Hygiene and Public Health," by Dr. Arthur Whitelegge; "Medical Hand-Book for Colonists," by E. Alfred Barton; new editions of "Climate and Health Resorts," by Dr. Burney Yeo, and "The Story of the Heavens," by Sir R. S. Ball; "The Art of Cooking by Gas," by Marie Jenny Sugg, illustrated; "Nature's Wonder-Workers: being some Short Life-Histories in the Insect World," by Kate R. Lovell; "Object Lessons from Nature: a First Book of Science," by L. C. Miall; "Commercial Botany of the Nineteenth Century," by J. R. Jackson; two new volumes of "Cassell's Agriculture Series," edited by John Wrightson—"Soils and Manures," by Dr. J. Munro, and "Crops," by Prof. Wrightson; and "The Year-Book of Treatment for 1891: a Critical Review for Practitioners of Medicine and Surgery."

Messrs. Whittaker will publish a new and revised edition of Mr. Gisbert Kapp's "Electric Transmission of Energy"; "Electro-Motors," by S. R. Bottone: "Metal Turning," by the author of "Practical Ironfounding"; a fourth and popular edition of Colonel Findlay's "The Working and Management of an English Railway"; and "A Manual of Wood-Carving," by Charles G. Leland.

A work on "Animal Life and Intelligence," by Prof. C. Lloyd Morgan, Dean of University College, Bristol, is in the press, and will be published by Mr. Edward Arnold in October.

Mr. Stanford will publish "The Philosophical Basis of Evolution," by Dr. James Croll, and "Through Magic Glasses" by Arabella B. Buckley (Mrs. Fisher). This will be a sequel to the same author's "Fairyland of Science."

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 22.—M. Duchartre in the chair.—Account of a scientific expedition to the summit of Mont Blanc, by M. J. Janssen. (See Our Astronomical Column.)—On the modular equation for the transformation of the eleventh order, by Prof. A. Cayley.—On some curious phenomena produced in a current of water, by M. Daniel Colladon. The author presented two photographs taken at Geneva above a river bridge having a grating stretched across its arches. By moving certain of the bars, miniature water-spouts and other phenomena are produced. These forms are conspicuously visible and have been photographed in plan and elevation. The paper contains some observations of their average dimensions.—M. Berthelot announced the death of M. F. Casorati, Professor at the University of Pavia.—Observations of the new minor planet (297) made with the equatorial *coudé* of Algiers Observatory, by M. F. Sy. The observations extend from September 11 to 13.—On the electrical resistance of metals, by M. H. Le Chatelier. The accompanying figure expresses the results obtained with various metals and alloys:—

On the excretory apparatus of some crustacean decapods, by M. Paul Marchal.—Comparative influence of anæsthetics on chlorophyllian assimilation and transpiration, by M. Henry Jumelle. The researches of the author seem to show that anæsthetics increase the transpiration of plants exposed to the light, when sufficient is given to suspend assimilation. This increase of transpiration is evidently due to the action of the ether on the chlorophyll which is exposed to the light, because, from experiments made in the dark, it has been found that the ether acts in an opposite manner on the protoplasm.

Sydney.

Royal Society of New South Wales, June 4.—Dr. Leibius, President, in the chair.—The following papers were read:—A compressed air-flying machine, by L. Hargrave.—On the treatment of slips on the Illawarra Railway at Stanwell Park, by W. Shellshear.—On native names of some of the runs, &c., in the Lachlan district, by F. B. W. Woolrych.—Remarks on a new plant rich in tannin, by C. Moore.—The following exhibits were shown and described: two new filmy ferns, by C. Moore; the Narraburra meteor found in 1854—specific gravity 7·57, weight 70 lbs. 14 oz., by H. C. Russell, F.R.S. (of which an account was given in Nature of Sept. 25, p. 526).

July 2.—Dr. Leibius, President, in the chair.—Record of hitherto undescribed plants from Arnheim's land, by Baron Ferd. von Mueller, F.R.S.—A new mode of demonstrating the manner in which the mind judges of objects in the outer world, also working models demonstrating the value of the spinal curve in diminishing the evil effects of mechanical violence, by Prof. Anderson Stuart.—Charles, third Earl Stanhope's arithmetical machine, bearing date 1780, also his "demonstrator," an instrument for the performance of logical operations, by Rev. Robert Harley, F.R.S.

THURSDAY, OCTOBER 9, 1890.

A NEW THEORY FOR THE SENSITIVE PLANT.

Das reizleitende Gewebesystem der Sinnpflanze. By Dr. G. Haberlandt. (Leipzig: W. Engelmann, 1890.)

THE present decade has been a very important one from the point of view of a botanical revival in this country. The seed sown in previous years by Thiselton Dyer and others did not fall entirely on sterile soil, and gradually a school of active workers has arisen, sometimes described, for want of a better name, as "the younger school of botanists." The individuals constituting this "school," though few in numbers, have pursued widely diverging lines of research; some devoting themselves to morphology, others to physiology and minute anatomy, others again to the diseases of plants, &c. Important results have accrued from their labours in the various branches taken up, but in no case have they been more striking than in the field of minute cell anatomy. The readers of this journal hardly need to be reminded that the discovery of the continuity of the protoplasm from cell to cell, and the demonstration of the fact that plant tissues do not consist of a number of isolated masses of protoplasm, cut off from one another by the dead cell-membranes, was largely due to the investigations of Gardiner.

The knowledge of the existence of these uniting filaments seemed from the first to throw light on many intricate and obscure physiological problems. Foremost among these was the possibility that by their instrumentality the transmission of stimuli over considerable tracts might be facilitated. It is interesting to remember that almost the first case of continuity of protoplasm demonstrated by Gardiner was that in the pulvini of the leaves and leaflets of the sensitive plant. Nor did this lose its significance when it was later realized that such a continuity was a very general, if not universal, phenomenon in plant tissues. The view that the stimuli, which undoubtedly travel considerable distances in most of the plants endowed with irritable movements, are transmitted in virtue of these exceedingly fine uniting filaments is one very generally held by botanists in this country, and finds expression in Vines's "Lectures on the Physiology of Plants." Indeed, that this is so, in certain cases, has been experimentally demonstrated. In view of these circumstances, the book whose name heads this review, dealing as it does entirely with the mechanism of stimulus transmission, will be studied with interest, and the more so from the fact that Dr. Haberlandt's "Physiologische Pflanzenanatomie" has done much towards the elucidation of many of the facts of anatomy. Dr. Haberlandt here limits himself solely to the investigation of the means by which a stimulus, set up at some point in the sensitive plant (*Mimosa pudica*), is transmitted to a distance, promoting movements in regions far removed from the point stimulated.

During this century various physiologists have busied themselves with this problem, notably Dutrochet, Pfeffer, and Sachs. The prevalent theory on the Continent, which is associated especially with the name of Pfeffer, briefly amounts to this:—When an irritable portion of one of the pulvini of the sensitive plant is stimulated, the irritable cells lose their turgidity, water passing out of them into the intercellular spaces associated with them; a certain amount of this water is said to enter the tracheides and vessels of the xylem of the vascular bundle, and to upset the hydrostatic equilibrium obtaining there; this disturbance is transmitted to a distance as a wave in the xylem, and stimulates, as it travels along, the irritable cells of the successive pulvini which it passes near, causing them likewise to contract. This may affect merely the pinnules of a single leaf, or, in certain cases, the stimulus may travel from one leaf to another.

This hypothesis is based on very old experiments performed by Dutrochet more than sixty years ago. Dutrochet found that, (1) after the removal of a complete ring or zone of cortical tissue from the stem, a stimulus could still be propagated from one leaf to another, across the decorticated region. A similar result followed when the pith was destroyed, the vascular bundle alone being left intact. The irresistible inference was that the stimulus travelled by the *vascular bundle*. Further, (2) when the woody portion of the bundle was cut into, a drop of liquid was observed to exude immediately, and a stimulus was transmitted upwards and downwards from the point of lesion, causing movements in the nearest leaves and even travelling to more distant ones. The drop which exuded was supposed to come from the wood, and the disturbance of pressure resulting, to initiate the stimulus. Haberlandt deals with this "fundamental experiment," and shows that Dutrochet and the others were in error. To make this clear, it is necessary to briefly indicate the structure of a bundle and adjacent tissues in *Mimosa pudica*. In a transverse section of a stem (and the same holds generally for the petiole) there is externally the epidermis, below which comes the parenchymatous cortex. The cortex passes over into a zone of thick-walled cells, described as collenchyma by Haberlandt, as bast-fibres by some other writers. Within this thick-walled zone is a ring of phloem, and finally the xylems and pith. Dutrochet, when he thought he had dissected away all the tissues outside the xylem in the experiment recorded above (1), had, in point of fact, left not only the phloem, but also the collenchyma-ring intact. His knife had been arrested by the collenchyma, which he had mistaken for the wood. The collenchyma and phloem remained intact, and the inference that the stimulus travelled by the xylem was consequently a false one.

Further, in the case of experiment (2), Haberlandt is at great pains to show that the drops of liquid do not issue from the wood at all, and establishes the fact that they arise in reality from special cells in the phloem. Following the same method of experiment as Dutrochet, Meyen, and Pfeffer, Haberlandt demonstrates clearly—

(1) That the stimulus normally travels inside the collenchyma ring, but outside the xylem of the bundles; in other words, in the phloem.

(2) That, when a stem is cut through, drops exude at the moment of cutting. These drops arise, not from the xylem, but from special cells in the phloem.

This alone marks a considerable advance on the older hypothesis.

Having cleared the ground so far, Haberlandt sets himself two problems for solution, and it is with these that the greater portion of his paper is occupied. These questions are :—

(1) What are the special organs in the phloem which transmit the stimulus?

(2) What are the details of the mechanism of transmission?

As his later inferences and experiments are based on a detailed anatomical study of the sensitive plant, it will be advisable to follow Haberlandt into this matter. The phloem of many Leguminosæ is characterized by the possession of rows of cells, somewhat larger than the true sieve-tubes, which, from the nature of their contents, are known as tannin-sacs. These, in *Mimosa pudica*, are long, tube-like cells, arranged end to end. Each cell possesses a primordial utricle and a large nucleus. The longitudinal walls of these cells are frequently pitted, but the structure of their transverse walls is characteristic. Each possesses a very large, shallow pit. The closing-membrane of the pit is traversed by a number of very delicate protoplasmic filaments. These are much finer than the similar connecting filaments of sieve-tubes, and approximate more nearly to the uniting filaments of adjacent parenchyma cells. Haberlandt shows that it is a portion of the watery content of *these* cells which escapes, when a stem or petiole is cut into; and it is his view that these cells constitute the organs which transmit the stimuli from one point to another in the plant. The watery fluid which exudes from them, usually clear and colourless, gives a very characteristic, and deep reddish-violet colour, with iron chloride, and, if allowed to dry upon a slide, crystallizes out in various forms, usually arranged as sphere crystals or dendritically. This substance is probably of the nature of a glucoside, since, among other reactions, when treated with acids it is broken up into glucose and a resinous body. Accompanying this glucoside is a considerable amount of mucilage.

The distribution of the vascular bundles, in especial relation to these supposed conducting cells, both in leaf and stem, is followed out in detail. The glucoside-containing cells occur, roughly speaking, in two rings in the phloem, one of which is nearer the collenchyma zone, the other nearer the xylem. Some of the former actually touch the collenchyma cells. Where the bundles traverse the pulvini, a much larger proportion of these cells are in contact with the collenchyma. In the leaflets all the larger bundles are accompanied by the glucoside-containing cells, but in the very small anastomoses they die out. Finally, as to the distribution of protoplasmic continuity. This obtains in the soft cortex and in the collenchyma (whose cells are freely pitted). The cells of these two tissue systems are united together by extremely fine filaments in such a manner that an unbroken protoplasmic continuity exists, from the periphery of the pulvinus to the inmost layer of the collenchyma. In the phloem also there exists a similar continuity. Between these two systems, however—the soft cortex and collenchyma on the one hand, and the phloem (including the glucoside cells) on the other—there is, according to Haberlandt, no direct continuity; and although the collenchyma cells are freely pitted on all sides, the closing-membranes of these pits are untraversed by protoplasmic filaments on the side directed towards the phloem (and glucoside cells).

By careful experiments, referred to above, Haberlandt demonstrates (what had been regarded by several observers as probable) that the stimulus travels in the phloem; and in view of the fact that the glucoside sacs emit the drops of liquid on cutting a stem or petiole (thus giving rise to a hydrostatic disturbance), and in view also of inferences drawn from further experiments, to be considered immediately, Haberlandt concludes that the stimuli are transmitted by the rows of glucoside-containing sacs, and this in a purely mechanical manner. Before going on to elaborate his theory, Haberlandt meets and disposes of the hypothesis, mentioned at the commencement of this review, that the stimuli travel from cell to cell by the agency of the uniting filaments of living protoplasm. According to that view, when any pulvinus is stimulated, as by a mechanical shock, its irritable cells contract, losing their turgidity, and a movement results; at the same time the stimulus would be conveyed to the phloem, and there transmitted from cell to cell by the filaments of protoplasm (it is immaterial whether in the phloem-parenchyma, or even in the longitudinally-running series of glucoside sacs) until it reaches another pulvinus, where it would be communicated in the same way to the irritable cells there, and a further movement would result, and so on.

It is necessary at this juncture to explain, so as to make what follows intelligible, that physiologists have availed themselves of two entirely different methods of stimulating the plant—firstly, by submitting a pulvinus to a mechanical shock, without damage to its tissues; and secondly, by cutting the petiole or stem, and causing actual lesion of the conducting tissues. In both cases the stimulus is transmitted, but in the latter to a much greater distance, the method being altogether a more violent one and perhaps quite different in its effects. Pfeffer was content to regard anything of the nature of a "vital" hypothesis of stimulus-transmission as disproved, from the fact that, even when he chloroformed a definite portion of a petiole, a stimulus could still be transmitted through the region subjected to the chloroform. Haberlandt, however, points out that this result must not be taken as final, since there is no proof that the internal tissues had been really acted on by the anæsthetic, as applied by Pfeffer. Further, Vines has pointed out that, although chloroform deprives the *irritable cells of the pulvinus* of their irritability (rendering them rigid), there is no justification for the assumption that it likewise deprives the protoplasm of the *conducting cells* of their conductivity; an objection the validity of which is admitted by Haberlandt. It was necessary, therefore, to make a more crucial experiment to decide this point, and this Haberlandt does by substituting an *actual killing* of the protoplasm in a small portion of a petiole for a mere chloroforming. This was done by steaming a confined zone of a petiole. Under these conditions, the stimulus, to be transmitted successfully, had to pass through a dead region. If the stimulus could be shown to traverse this region, the "vital" hypothesis would be untenable. The

result was most instructive. When an ordinary mechanical stimulus was applied, there was no transmission; when, however, a stimulus, caused by a lesion of the tissues, was applied, it was transmitted, in the majority of cases, over the zone previously killed by steam. From this, Haberlandt concludes that no theory which depends on filaments of protoplasm to conduct the stimulus can be maintained. He considers it improbable that a mechanical stimulus and one due to lesion should travel in different ways, notwithstanding the fact, which he mentions later on, that under special conditions a stimulus can be transmitted even by the vessels and tracheides of the xylem. There is nothing surprising in the transmission over a dead region of a stimulus due to lesion. It is just this sort of stimulus that would cause a considerable upset in the hydrostatic equilibrium in the glucoside cells cut into, and it is conceivable that the disturbance due to this sudden fall in pressure might be conveyed, in a purely mechanical manner, over considerable distances. Hitherto it has not been shown that a *normal mechanical stimulus* can be transmitted over a zone that has been rendered incontestably dead.

If the distribution of the continuity of protoplasm in a pulvinus should be, as stated by Haberlandt, such that the outer system of continuous cells extends inwards only so far as, and including, the collenchyma, and that the phloem is independent of this system, then it is difficult to see how the stimulus could pass (by a vital hypothesis) from the irritable and contractile cells to the conducting cells. This result, however, requires confirmation. Gardiner, who investigated the nature of the continuity in these organs of the sensitive plant, makes no comment on any such marked discontinuity of the protoplasm, and the inference, drawn from a study of his paper in the Philosophical Transactions, is that the cells, from the periphery right up to dead vessels of the wood, constitute one connected whole. What he denies to the sensitive plant, Haberlandt admits for other cases. The phenomenon of transmission of stimuli in the stigmas of *Mimulus* and *Martynia*, in the leaves of *Dionæa* and probably of *Drosera*, and in the tendrils of many climbing plants, would seem to be a function of the protoplasmic fibrils. Having dealt with his refutation of the "vital" hypothesis, as applied to the sensitive plant, we may give a short summary of the theory put forward by Haberlandt, though for its details, and the many questions raised therein, the reader is referred to the original text. Haberlandt holds that both in the case of a mechanical stimulus, and in that of one caused by a lesion of the tissues, the transmission is effected in a purely mechanical manner, as a wave or impulse passing along the glucoside-containing cells. Necessarily the transverse walls, which possess each a broad, shallow pit, are regarded as offering little resistance to the filtration of the contained sap. The protoplasm which is continuous through these pit-membranes is not regarded as playing an important part in this event. When a pulvinus is mechanically stimulated, its irritable cells lose water and contract; the disturbance set up by this fluctuation in pressure will start a wave in the rows of conducting cells, travelling from the point at which the increase of pressure occurs. The wave is what may be described as a positive wave (*Bergwelle*), and the method of its transmission is similar to that obtaining in a closed rubber tube distended with water, when it is pinched at one end. This wave, when it reaches the irritable cells of the next pulvinus, will be communicated to them through the elastic collenchyma layer, probably through the pits, which are numerous. In more sluggish cases it may not, perhaps be till an actual *bending* occurs in the stimulated pulvinus that the increase of pressure will be sufficient to start the wave in the conducting cells.

On the other hand, when the stimulus is due to lesion, as when a petiole or internode is cut into with a sharp knife, the wave is set up in a different manner. At the moment of cutting into the turgid, glucoside-containing cells, a drop of liquid escapes, causing a *fall* in pressure. This is transmitted as a negative wave (*Thalwelle*), and will be communicated to the irritable cells at a distance, by the agency of the pits there. In this case, however, the pit-closing membranes of the collenchyma will bulge slightly inwards, in the former case outwards. The communication from the conducting to the contractile cells is rendered easier from the fact that in the pulvinus a much larger proportion of the former lie adjacent to the collenchyma than at other points on the course of the bundle. This special arrangement undoubtedly seems to favour such a theory as that of Haberlandt. Still it must be remembered that it may be due to quite different causes. As is well known, the arrangement of the bundles is always considerably modified at the pulvini, so that the bending may be interfered with as little as possible.

In conclusion, it must be admitted that the paper here reviewed is a masterly piece of work, though, it may be, many naturalists in this country will hardly agree with the author in the inferences which he draws, and the theory which he builds upon them. It must be borne in mind that possibly too important a part may have been assigned to the uniting fibrils of protoplasm as touching the transfer of stimuli of various kinds from cell to cell. In the first blush of a great discovery, of so far-reaching a nature as that of the continuity of protoplasm, and more especially from the fact that at a very early period it was in the sensitive pulvini that this continuity was shown to exist,—in view of this, the position that has been taken up by workers in this country may have been an over-sanguine one. It may be that the explanation of this phenomenon of protoplasmic continuity (though undoubtedly it facilitates transmission of stimuli in certain cases, *e.g.* stigmas of *Mimulus*, &c.) may have another bearing—that it may in some way affect the nutrition of the pit-closing membrane, or even discharge the purely mechanical function of binding the protoplasts to the closing membranes. For the present, although it must be conceded that Haberlandt has considerably advanced our knowledge of this question, in that he has localized the conducting region to the phloem, and has shown that stimuli due to actual lesion can be transmitted in a purely mechanical manner; nevertheless he has failed to demonstrate conclusively the untenability of the "vital" hypothesis in the case of the normal stimulus (*Stossreiz*). This being so, further results must be awaited before this interesting question can be regarded as finally settled.

F. W. O.

CHRISTY'S "BIRDS OF ESSEX."

The Birds of Essex: a Contribution to the Natural History of the County. By Miller Christy, F.L.S., 8vo. (Chelmsford and London: 1890.)

"HITHERTO," truly observes the author of this work in his Preface, "the birds of Essex have not found a chronicler. It is to supply this omission that I have laboured." The omission has indeed been long regretted, and every page of his book shows that Mr. Christy has laboured hard to supply it, so much so that it would seem an act as ungenerous as it is certainly unpleasing to find any fault with him for the way in which he has performed his task; but the duty of a reviewer is one neither to be lightly entered upon nor lightly executed, and misplaced tenderness may easily be as harmful in a critic as in a surgeon.

There is fortunately in these days no need to dwell on the advantage of county ornithologies—even the worst of them is better than none at all. Mr. Christy's is very far from being among those that are bad; but it does seem to us that more skilful treatment would have secured for Essex a less insipid result than he has given us; for the county of the greatest English naturalist should surely present a more becoming figure than here appears. Its geographical position, its sufficiently varied natural features—and among them especially its wealth of estuaries, so grateful to scores of graceful birds—seem to point it out as one of the most favoured parts of the kingdom. We can hardly admit the value of Mr. Christy's supposition (pp. 2, 3) that—

> "If only our illustrious Ray had made some attempt to produce a list of local birds, similar to that of his contemporary, Sir Thomas Browne, there is no saying how many practical Essex ornithologists it might indirectly have brought out, or to what a pitch of ornithological eminence the county might by this time have been raised."

When will naturalists think the history of their study worth studying? Nothing can be more certain than that the now celebrated "Account of Birds found in Norfolk," by Sir Thomas Browne, remained in manuscript until printed by Wilkin in 1835; and, while very few could have been aware of its existence, fewer still could have read its crabbed handwriting. As a matter of fact, we believe it was unknown to every ornithologist until it was published. On the other hand, Mr. Christy shows that almost from Ray's time to the present day Essex has not been wanting in observers of birds, who really seem to have had it in them to do as much good work as those of the not very distant and more northern county, whom he evidently and not unjustly regards with a kind of modified envy. But our author may get some comfort by looking southward across the wide Thames, and there contemplating in a still nearer neighbour a county whose ornithology, as we have before remarked in these columns, is yet unwritten as it should be.

Mr. Christy rightly remarks that "some detailed attempt" to describe the physical features of every county or district should be an essential part of each local "avifauna," but he unfortunately favours us with barely three pages of such description. Now we are sure that he might have told us a good deal more on this subject that would have been well worth knowing. He divides his county into *five* districts, which is doubtless well enough, if we can forgive the incongruity of the last:—(1) The Chalky Uplands, (2) The Lowlands, (3) The Forests and Woodlands, (4) The Marshes and Saltings, (5) The Open Sea! The first of these, a very small but well-defined area, has probably, through enclosure and tillage, undergone more change within the last 70 or 80 years—or even less—than any of the rest; for the second has been highly cultivated for centuries, and the third—though Mr. Christy thinks that strictly speaking it cannot be separated from the second—in some sort possesses the appearance it must have worn (if not the fauna it harboured) in the middle ages when, if we may believe the chroniclers, the citizens of London went forth to slay wild bulls and wild boars within its precincts—a trace of the practice being retained in the "Epping Hunt" of Easter Monday, which some of us are old enough to remember, and others may be reminded of by Hood's comic verses. But the fourth of Mr. Christy's districts may be considered the most characteristic of Essex, and we think he might advantageously have told us much more about it, especially about the islands—if islands, except in popular speech, they may be rightly called—into which the land, as it were, breaks up—Canvey, Foulness (a most suggestive name), Osea, Mersea, and others. One would think they cannot be all alike, and would like to know wherein they differ. The same may be said of the rivers—and the rivers of Essex are rather fine things in their way; the many-mouthed Crouch is not exactly similar to the spacious Blackwater, any more than is the narrow Colne (in happier times glorying in its abundance of "natives") to the lake-like Stour, which the county shares with Suffolk. As to the fifth district, only a technical objection could be raised, and that would be against the use of the epithet "open." A maritime county must have a sea-border, and it stands to reason that a fair portion of the adjacent salt water should be regarded as *adscriptus glebæ*, but no attempt is made to define that portion. Considering the shallow soundings off the Essex coast, perhaps the political "three mile limit" might be the best to choose; but again, considering the paucity of bird-life in the summer time in this narrow sea, and the knowledge that in winter one part of it is nearly as good as another, this does not much matter, and if Mr. Christy would extend his survey to the halfway line between England and Belgium, there is none to take exception thereto. In truth Essex, owing to its want of cliffs—for there is nothing save near Walton-on-the-Naze entitled to be so-called—and of beaches, such as those of Orford or Dungeness possessed by its neighbours, has nowadays nothing except the Little Tern,[1] that can be called peculiarly a shore-bird, for he properly denies (pp. 100, 101) the claim set up by the late Dr. Bree for the "Mud-lark" (*Anthus obscurus*), and, as all ought to know, the Ringed Plover will breed far inland; but we think he has missed an opportunity in not applying to the Migration Com-

[1] There can be hardly a doubt that the Common and perhaps the Sandwich Tern bred formerly on the Essex coast, but everyone knows how easily a settlement of either may be destroyed in a few hours by some heedless person who thinks himself a sportsman or a naturalist—so that all around our shores both species are being yearly extirpated from spot after spot. Mr. Christy's evidence (pp. 261, 262) as to the Black Tern, not that it is littoral species, breeding in the county, amounts to nothing if properly scrutinized.

mittee of the British Association for the schedules filled up by the light-keepers on the coast of his county. The necessary documents would doubtless have been readily placed at his disposal, and comparatively meagre as the results might have been, they would certainly have enabled him to give a considerable amount of additional information.

Like most of his fellows, Mr. Christy attaches an undue value to the number of species he is able to register, and his number is 272. We have often wished there would arise some strong-minded man who would clearly distinguish between a member of a fauna and a fortuitous straggler. Still, we gladly allow our present author to be more discriminative than many of his brethren, and highly applaud his exclusion of several species which they, or some of them, welcome—yet he more than once bows the knee to the prevailing Baal. It is bad enough for any British faunist to admit one species of Sooty Tern; especially when the alleged single specimen rests on authority not quite beyond suspicion, and, though not ten years have elapsed, has been "entirely lost sight of"; but the inclusion of a second species dulls one's feelings, like an anæsthetic—especially when we are told that in this case it is the captor "who has since been lost sight of" (p. 261), though the specimen is (apparently) to the fore. Then, again, what can be more absurd than the admission of *Porphyrio smaragdonotus* (p. 225)—a species of which living examples are yearly imported in great numbers, and one that possesses faculties of escaping from confinement that would have been envied by a Casanova or a Baron Trenck.

It may be urged that we have picked out trifling faults, but we could reply that we have purposely chosen these instances to show two at least of the failings of faunists. Others we might specify of a rather different kind. It is a remarkable fact for ornithologists in general that the Needle-tailed Swift should have flown across the Old Continent from Eastern Siberia to Essex, but that fact does not make it a "British" bird, and the late Mr. Yarrell—generally too prone to naturalize all stragglers—was in our opinion perfectly justified in refusing it a place in his well-known work, while even the subsequent occurrence of two examples in Hampshire does not affect his rejection of it. As regards the inclusion of "stragglers," the line is in many cases hard to draw, but in one such as this there ought to be no doubt in the mind of anybody who has a decent acquaintance with the geographical distribution of animals.

The present work differs of all others of its kind in two respects, and one of them is deserving of much praise. This is the useful "Biographical Notices of the principal Essex Ornithologists," which are greatly to the point, and generally, as appears to us, well done, though Mr. Christy is somewhat lavish of the expression "excellent ornithologist." That would doubtless be applicable to John Ray, who is not included, but in its literal sense to few if any others. Yet men like Sheppard, Hoy, and Henry Doubleday were worthies who left their mark on British natural history, and fully merit all that is said of them, while Christopher Parsons seems to have been one of those diligent observers who delight in hiding their candle under a bushel, and we feel under an obligation to Mr. Christy for bringing him out of obscurity.

Of the other distinctive feature of the work we cannot report so favourably. It is the needless introduction of a considerable number of figures representing the birds mentioned. Some of them, it is true, are reproductions of Bewick's well-known woodcuts, and therefore right in the main, however poor the imitation. Next, if not equal to them, are the few drawn by Mr. Wolf; but the adaptations of the engravings from Yarrell's work, if they cannot be called absolutely bad, are objects about as disagreeable as one ordinarily encounters, and there are others, the source of which we cannot divine, that make one shudder, for the draughtsman has evidently copied too faithfully (as the manner is nowadays) the distortions of the bird-stuffer—as witness the figure of the Swift (p. 144), which reminds one forcibly of the impossible tenants of the air in the familiar willow-pattern plate.

To sum up, let us say that with all its shortcomings Mr. Christy's book is one that must demand the attention of every British ornithologist, for it "means business." There is no attempt at fine writing in it, and yet its composition has clearly been a labour of love to the author. We trust he may be rewarded by a successful sale, which the populous county of Essex ought to insure, and be able to bring out a new edition. If so, let him eschew his woodcuts, and in their place give us more large type.

HYPNOTISM.

Hypnotism. By Albert Moll, of Berlin. "Contemporary Science Series." Edited by Havelock Ellis. (London: Walter Scott, 1890.)

THIS book by Dr. Albert Moll, a physician of Berlin, on hypnotism, now presented to us in a becoming English dress, marks a step of some importance in the study of some difficult physiological and psychological problems which have not received much attention in the scientific world of England. The appearance of a text-book on any subject in a set of hand-books such as the "Contemporary Science Series," indicates a general agreement on the main points of knowledge, and in this case a full admissal of the subject to the category of recognized science. Dr. Moll's work has already been widely accepted as a text-book in the German schools which are beginning to take some interest in his subject. The first edition was published hardly eighteen months ago, and was very rapidly exhausted; the second, from which this English translation has been made, shows good proof of the diligence and care of the author, in the large amount of new matter incorporated with the old, so that on the whole it is well up to date, a matter not so easy to accomplish in treating of a rapidly growing subject such as hypnotism, on which nowadays there are published some 300 books, pamphlets, and articles every year. There has often been in this crowd of minor literature of late years a tone of somewhat indignant, sometimes injured self-assertion, such as is not unnatural to the friends of a young branch of knowledge, who are anxious and perhaps over-anxious to establish its position on equal terms with its seniors. But Dr. Moll's hand-book embodies an essentially non-combative survey of the full breadth of the subject, including both the details of the physical and physiological conditions of hypnotism on the one side, and on the other the alterations of personality and the more delicate points of

psychological interest; and it does not refuse to consider with some careful attention the phenomena of telepathy and thought transference in a hypnotic state, such as are judged by Charles Richet, Gurney, Pierre Janet, Oliver Lodge, and others to take place under conditions which render their explanation by the action of the known senses at present inadequate.

Such a comprehensive review of the present position is in need of a far more extensive and careful historical preface than is usually undertaken; and in this respect Dr. Moll has shown his sense of his responsibilities, and gone much beyond a mere reproduction of the hackneyed account of many of the French writers. He sees that the phenomena generally called mesmeric did not entirely originate with Mesmer (1734–1815), about a century ago; but can be in part traced back to some of the earlier civilizations (cf. Ebers's papyrus, 16th century B.C.), and assumed some of their more modern forms under Paracelsus (1493–1541) and van Helmont (1577–1644), although, of course, their recent growth has been far more rapid. Mesmer is a man hard to estimate rightly. The final account of him has probably not yet been written, nor the final judgment passed, but Dr. Moll furnishes a sketch of some discrimination, based chiefly on contemporary evidence, and showing some sympathy for the mental and moral bewilderment occasioned by the chaos of the Great Revolution with which he was surrounded in Paris. Since Mesmer, he realizes the steps in advance made by Braid (1843), in recognizing the physiological and psychological importance of a state of attention in what he called no longer mesmerism or animal magnetism, but hypnotism; by Esdaile in 1845, in demonstrating the complete anæsthesia that was made possible by hypnotism, even in major surgical operations; by Liébeault (1866), in showing the practical use of post-hypnotic suggestion to dominate at least some morbid habits and minor pains; and by the schools both of the Salpêtrière under Charcot (1878) and of Nancy under Bernheim (1884), in proving to the general public the permanent importance of a deeper study of the subject.

The survey of the methods of induction and the symptoms of hypnotism is founded on much personal experiment and a wide experience in all the European nations. More than 600 authors are quoted, and more than half of these are contemporary. Though fully half of them come from France and Germany together, yet there is a very considerable total of English, Swiss, Austrians, Americans, Italians, Spaniards, Belgians, Dutch, Swedes, Danes, Greeks, and Russians. Hypnotism is certainly not a limited or local fancy. Last year the four days' discussion of hypnotism under its various aspects at the Congrès International de Psychologie Physiologique, in Paris, by such a large gathering of men from all parts of Europe, not interested merely in the medical side of the subject, but in its total results and their relation to other branches of knowledge, gave very tangible proof of this, as may be seen in their *Compte rendu*. And who are the easiest persons to hypnotize? It is very common to find those who have had little or no experience themselves confident that they can point out the most amenable subjects, and choosing generally persons with some obvious weakness. But Dr. Moll shows that neither neurasthenia nor hysteria, nor weakness of will, nor any of the sentimental weaknesses that may be made to render their subjects laughable, really conduce to making them more readily hypnotizable. Hysterical people may be morbidly imitative, and if one is hypnotized many may follow the example, if it is open to their observation; but taken singly, their hysterical tendencies rather hinder than help their hypnotization (p. 316), a point which has unfortunately been rather obscured by the long and important experiments made by Charcot on the hysterics only; for, from the success of many of these, it was hastily and incorrectly assumed, before wider trial, that this class of subject was the most easily influenced. Whether there can be any special capacity in the hypnotizer is a point Dr. Moll does not discuss in detail; he assumes that all of fairly good intelligence are about equal after a little practice at the *technique*. But there are some cases which he mentions (p. 363), of hypnotism at a distance by Dr. Gibert and Pierre Janet, in which, when both the persons hypnotizing and the times of hypnotism were unknown to the subjects, certain persons proved pre-eminently successful (*Bulletins de la Société de Psychologie Physiologique*, 1886, p. 78). The proof or disproof of individual qualifications is, in fact, one of the many difficult points for the settlement of which a wide and very careful experimental research is still necessary. The mesmerists of the early part of the century can be shown to have laid too much stress upon it; it may be that it is too much overlooked now.

Any exact definition of hypnotism, as of other abnormal states of consciousness, is difficult enough, as Dr. Moll very readily acknowledges. "The two characteristics of hypnosis are suggestibility and the power of ending the state at pleasure" (p. 208), he observes, in agreement with most others who have considered the subject; but it is not plain how this is consistent with what he has said just before (p. 201), viz. that "to my mind the dividing line between sleep and hypnosis is merely a quantitative difference in the movements." The mental susceptibility would have seemed to us a more important point of variance. But we are glad to say that, on the more difficult points of theory, Dr. Moll promises us another book at some future date, and it seems wise to allow some considerable time for the collection and attestation of the phenomena before attempting the establishment of theory in matters of such traditional difficulty.

That the practice of hypnotism is very useful in the healing art Dr. Moll is convinced, and offers a good deal of technical medical evidence which it would be hardly appropriate to consider here. The power of post-hypnotic suggestion in checking habits of drunkenness, &c., is one which is just beginning to be confirmed from various quarters, and which opens a wide vista. The possible dangers which arise from the hypnotist's power over the patient's conduct need very careful attention, though Dr. Moll is inclined to point with satisfaction to the very few cases in which any injury has been actually done. We could have wished that he had made plainer that most important preventive practice of Liébeault's, viz. that those who are afraid of the dominion of any hypnotist can be and should be protected against it by hypnotization under other trustworthy hands, and by the suggestion that no one can have any hypnotic or post-hypnotic power over them. In his last chapter on

animal magnetism, Dr. Moll practically admits an unexplained residuum of facts, and in the candid temper of his whole book, shows a truly scientific spirit of genuine interest in their investigation.

A. T. MYERS.

OUR BOOK SHELF.

Text-book of Mechanics. By Thomas Wallace Wright. (New York: D. Van Nostrand Company, 1890.)

THIS book is a most excellent treatise on the science of mechanics, and systematically places before the student the principles which underlie the subject. The differential calculus for the most part is used only when a clear advantage is gained by it, and in the earlier chapters of the work two courses are open to the reader, one with and the other without it. The author in a note rather regrets that words for the unit velocity and unit acceleration have not been proposed, as these would simplify matters: the Rev. J. B. Lock, in his late book on "Dynamics for Beginners," has proposed and used two very good words, "velo" and "celo," for unit velocity and unit acceleration respectively.

On the whole, the practical parts are treated more fully than is usual, and the examples throughout are of a very practical and typical character, and not mere numerical illustrations of formulæ. Many examples the author has treated by the graphical method of solution, but he adds a word of warning to the student against making it a complicated weapon for attacking all sorts of problems which are more easily solved in other ways.

Another important point alluded to is the use of approximate formulæ: the rigorous formula always precedes the approximate one, the latter being reduced from the former, so that the degree of approximation can easily be estimated.

The last two chapters deal with the statics and kinetics of fluids, or, as they are more generally known, hydrostatics and hydrokinetics.

Besides numerous examples there are plenty of figures and woodcuts, and scattered here and there are a few historical notes which give a lively interest to the subject.

W.

An Elementary Text-book of Heat and Light. By R. Wallace Stewart, B.Sc. London. (London: W. B. Clive and Co., 1890.)

THIS volume is one of the University Correspondence College Tutorial Series, which are written specially to meet the requirements of the various London University examinations.

Of the twenty chapters, the first ten deal with the principles which underlie the theory of heat, while the second ten treat of those of light. In each chapter the principles and laws on which the subject-matter depends are fully described, and under the heading of "Calculations" the author explains the various laws in mathematical form, concluding with examples worked out, and in many cases questions from well-known examinations. The chapters on light are treated in a similar manner. Those reading this work should be able to obtain a fair grip of these two subjects, the elementary principles being well and concisely expressed.

At the beginning of the second part of the book, on "Light," the author recommences the numbering of the pages, which we think is rather a mistake, as it is awkward in the first instance for reference, and in the second it has necessitated the use of two indexes. The illustrations, one hundred and fifty in number, are very good and accurate, and the work concludes with an appendix containing a paper of questions set at the London Matriculation examinations under the new 1888 regulations.

The Confessions of a Poacher. Edited by John Watson, F.L.S. (London: The Leadenhall Press, 1890.)

IN an editorial note it is stated that the poacher of these "Confessions" is "no imaginary being." Since that is so, it might have been well for Mr. Watson to explain the precise nature of his own functions as editor. It seems rather odd to find a poacher talking in this way:—"It was the fact that I had, during the small hours of the morning, stood alone on London Bridge. The great artery of life was still; the pulse of the city had ceased to beat. Although bred among the lonely hills, I felt for the first time that this was to be alone; that this was solitude. I felt such a sense as Macaulay's New Zealander may experience when he sits upon the ruins of the same stupendous structure." How much of this is the poacher's, and how much are we to attribute to the editor? The same question often suggests itself, and a good many readers, we suspect, will conclude that at least with the form of the "Confessions" the person supposed to be confessing has had very little to do. The book displays a curious and intimate acquaintance with some forms of animal life, and may be of service in fostering a liking for natural history. Unfortunately, however, grammatical rules are not always treated with the respect which is due to them. Says the poacher: "Whilst preparing my nets and wires, the dogs would whine impatiently to be gone." No doubt the poacher here means that he himself prepared his nets and wires, but what he says is that the dogs prepared them.

Examination Papers in Trigonometry. By George H. Ward, M.A. (London: George Bell and Sons, 1890.)

ONE hundred and twenty examination papers are given in this book; they are arranged progressively and seem to be well chosen, and will be found good substitutes for the questions in the various text-books which become familiar to the student on his second reading. Questions solely on book-work collected together at the end form a useful addition.

Blackie's Modern Cyclopædia. Vol. VII. Edited by Charles Annandale, M.A., LL.D. (London: Blackie and Son, Limited, 1890.)

THIS is the seventh volume of this useful and valuable essence of information, commencing with the word "Potamogeton" and reaching as far as "Skates." The articles on the various subjects are generally well treated, and every reader may find something of interest in them; numerous pictorial illustrations and maps are given. The references to printing, Prussia, railways, Rome, Russia, and Scotland are among the most lengthy in this volume.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Recent Classification of the Shrews.

DURING the present year some very important work has been done with the *Soricidæ*, the family of the Shrews. This has been mainly contributed by the well-known student of the group, Dr. George E. Dobson, F.R.S., the distinguished mammalogist. Dr. Dobson has just published the first fasciculus of Part III. of his work entitled "A Monograph of the Insectivora, Systematic and Anatomical" (Gurney and Jackson, London). This fasciculus deals entirely with the Shrews, it being a quarto illustrated by six fine lithographic plates fully illustrating the dentition of the *Soricidæ*, as its text, in the most admirable manner, presents their characters. Even a still more important paper by the same author appeared in the Proceedings of the

Zoological Society of London for February of the present year, and is entitled "A Synopsis of the Genera of the Family *Soricidæ*." Probably the most extensive collection of these interesting little mammals ever examined by a single investigator, came under the hand of the writer of the works just quoted, wherefrom to make his deductions. His classification is most complete and acceptable, and goes to show that the Shrews are first to be divided into two sub-families, viz. the *Soricidæ*, and the *Crocidurinæ*, the first being characterized by having their teeth red-tipped, while in the latter the teeth are white. Five genera make up the first sub-family—which stand, *Sorex*, *Soriculus*, *Blarina*, *Notiosorex*, and *Crossopus*. In the *Crocidurinæ* we find six genera—namely, *Myosorex*, *Crocidura*, *Diplomesodon*, *Anurosorex*, *Chimarrogale*, and *Nectogale*. This adds four genera to M. Milne-Edwards's list, and from the same omits the genus *Neosorex*. Dr. Dobson believes that "the red-toothed Shrews diverged from the white-toothed, development having proceeded on somewhat similar lines in the descendants of both according to similarity of environment and modes of life." Of Dr. Merriam's genus and type, *Atophyrax bendirii*, he says that "there are no leading characters which would enable one to define the genus, were I inclined to admit it in my synopsis."

It is refreshing in these days to meet with such classification, and such an able classifier—one who, as Dr. Dobson most emphatically does, draws good strong lines in taxonomy, and discourages the hair-splitting methods adopted by some mammalogists in these days. R. W. SHUFELDT.

Takoma Park, D.C., September 13.

Musical Sands.

IN reference to the note respecting Mr. Hyndman's query *re* sonorous sand (NATURE, October 2, p. 554) it may be interesting to him, and others, to know that in our own islands musical sand is by no means rare. In the second edition of my "Musical Sand," shortly to be issued, I shall give a list of the places at which it occurs in England, Scotland, Ireland, and Wales, showing that only *observers* are rare—not the sands.

My investigations since my paper was first published nearly two years ago have brought many new and interesting facts under my notice, not the least being that the musical sands at Studland Bay are always mute during an easterly wind. This I have been able to account for.

About three years ago I propounded a theory to account for the emission of these musical sounds from sands; briefly it is that they are the result of the rubbing together of millions of clean sand-grains very uniform in size: two such grains rubbing together would not produce vibrations audible to us, but the *accumulation* of such vibrations issuing from millions of surfaces, and, approximately, of equal length, would produce a note sufficiently powerful to be sensible to us.

This theory has long been published, and though it has been examined by some of our most eminent physicists, and tested in a variety of ways since, nothing has been suggested which has caused me to abandon it. I shall be pleased to send Mr. Hyndman a copy of my first paper on the subject.

Bournemouth, October 6. CECIL CARUS-WILSON.

With what Four Weights (and a Pair of Scales) can be Weighed any Number of Pounds from 1 to 40 inclusive?

WITH two weights four amounts can be weighed, viz. each weight and the sum and difference of the two.

With a third, in addition to these four, the sum and difference of each and the third can be weighed. Three weights therefore give 13 amounts. Similarly a fourth weight gives $13 + 2 \times 13 + 1$, or 40 amounts, exactly.

It is therefore evident that each amount must be arrived at by only one combination, and that the sum of the weights must be 40 pounds. To weigh 39 pounds, then, we shall clearly want a 1 pound weight. With 1 and 39 we can weigh 1, 38, 39, 40. For the next weight 2 clearly will not do, as 1 could be arrived at in two ways. Taking 3, we find that 1, 3, and 36 give us 1, 2, 3, 4, 32, 33, 34, 35, 36, 37, 38, 39, 40. Now to get 5 without getting any amount by more than one combination we clearly want 9, and this will be found to solve the question, the weights being 1, 3, 3^2, 3^3. A fifth weight of 3^4 will enable us to weigh any number of pounds up to 121, and so on.

F. R. F.

Protective Coloration of Eggs.

IN view of Mr. Grensted's letter to NATURE last year (vol. xli. p. 53), asserting the writer's belief that the egg of the red-backed shrike varies with the tint of the lining material of the nest, and of my own reply to this (same volume, pp. 129–30), I had intended this summer to examine as large a series of nests and eggs as possible, in order to verify or disprove my former observations. I have, however, been unable to devote any time to the matter; and have only obtained two nests—both from the neighbourhood of Evesham. In each of these, I must confess that Mr. Grensted's contention is borne out. The lining of one nest is dull brown in colour; and the eggs (5) are of a mouldy-brown ground-colour, tending towards dull green. The lining of the second is brighter in tone; and contains a small fragment of red flannel. The eggs (5) of this nest show the commoner flesh-coloured ground.

In spite of these two instances, I must hold to my former opinion, that the correlation of ground-colour and environment is very imperfect in the nests and eggs of these birds. Next year I hope to be able to examine a greater number of nests.

E. B. TITCHENER.

Mote House, Mote Road, Maidstone, October 2.

LUNAR PHOTOGRAPHY.

THE idea of employing the process invented by Daguerre and Niépce for the purpose of obtaining photographs of our satellite was first suggested by Arago in a report made to the Paris Academy of Sciences on August 19, 1839. Daguerre acted on the suggestion, but, in spite of a long exposure, he obtained only feeble impressions, in which all details were conspicuously absent (Arago, "Œuvres," vol. vii. p. 458). The first photographic representations of the moon may therefore truly be said to have been made by Dr. J. W. Draper in America by means of a Newtonian reflector of five inches aperture. The specimens were presented to the New York Lyceum of Natural History. The following is an extract from the minutes of that association:

"March 23, 1840. Dr. Draper announced that he had succeeded in getting a representation of the moon's surface by the daguerreotype. . . . The time occupied was 20 minutes, and the size of the figure about 1 inch in diameter."

Dr. Draper also wrote in September of the same year:—

"There is no difficulty in procuring impressions of the moon by the daguerreotype beyond that which arises from her motion. By the aid of a lens and a heliostat, I caused the moon-beams to converge upon a plate, the lens being three inches in diameter. In half an hour a very strong impression was obtained. With another arrangement of lenses I obtained a stain nearly an inch in diameter of the general figure of the moon, in which the places of the dark spots might be indistinctly traced" (*Phil. Mag.*, vol. xvii. p. 222, 1840).

In 1850, W. C. Bond, in conjunction with J. A. Whipple, a photographer of Boston, obtained some really good daguerreotypes of the moon. The instrument used was the equatorial of 15 inches aperture belonging to Harvard College Observatory, and images from two to three inches in diameter were obtained on plates adjusted at its focus. Some of these pictures on glass, and mounted for the stereoscope, were exhibited in London at the Great Exhibition of 1851, and also at Paris ("Annals, Observatory of Harvard College," vol. i. p. clvii.).

Also in 1850, Niépce de St. Victor obtained a strong impression of the full moon in twenty seconds on an albumenized glass plate sensitized with silver chloride. He had only discovered this photographic process a few months previously, and the plate was exposed in order to test the efficiency of the film employed. No attempt was made, however, to follow the moon's motion, so the pictured disk could hardly have exhibited the circular

outline of the object it portrayed (*Comptes rendus*, vol. xxx. p. 710, 1850).

After the discovery of the collodion process by Scott Archer in 1851, lunar photography grew apace. Warren De La Rue exhibited some photographs of the moon at the Royal Astronomical Society in 1853. With respect to these pictures he afterwards remarked: "At the latter end of 1852 I made some very successful positive lunar photographs in from two to thirty seconds on a collodion film, by means of an equatorially mounted reflecting telescope of 13 inches aperture, and 10 feet focal length, made in my workshop, the optical portion with my own hands, and I believe I was the first to use the then recently discovered collodion in celestial photography." No automatic driving motion was attached to the telescope, and the moon's motions both in right ascension and declination were followed by adjusting a sliding frame attached to the eyepiece holder, in the diagonal parallel with the moon's apparent path (Brit. Assoc. Rep., Aberdeen, 1859, p. 131).

In July 1853, Prof. J. Phillips obtained photographs of the moon 1¼ inch in diameter on a collodion plate exposed for five minutes in the first focus of a 6¼-inch refractor. Some of the pictures were exhibited at the Hull meeting of the British Association in September 1853, on which occasion Prof. Phillips read a paper "On Photographs of the Moon," and pointed out the many advantages to be gained by the development of lunar photography (Brit. Assoc. Rep., Hull, 1853, p. 14). He also dwelt on the desirability of using reflecting telescopes for the purpose because of the fact that in such instruments the chemical and optical foci coincide.

The Rev. J. B. Reade, the discoverer of many important improvements in photographic processes, made several not very successful attempts to obtain daguerreotypes, whilst Bond and Whipple were producing such pictures in America. Later, in 1854, by exposing a collodion plate for thirty-five seconds in the focus of a reflector having an aperture of 24 inches, a negative of the full moon was obtained from which enlargements 9 inches in diameter were made. These results were exhibited at the meeting of the British Association held at Liverpool in 1854 (British Association Report, 1854, p. 10).

Mr. Hartnup, of the Liverpool Observatory, in conjunction with Dr. Edwards and Mr. Forrest, also took some lunar photographs in 1854, by means of an 8-inch refractor, and exhibited the results at the above meeting (*ibid.*, p. 66).

Prof. Crookes began work with the same instrument in 1854, and his first step towards obtaining good negatives was the introduction of the purest chemicals. This, and a strict adherence to correct formulæ, enabled him to reduce the exposure from thirty to four seconds. The diameter of the moon's image in the first focus of the instrument used was 1·35 inch, and the negatives obtained bore an enlargement of twenty times, but on account of the proportional magnification of defects in the film, the results were not perfect. To eliminate defects arising from this cause, Prof. Crookes suggested that "The magnifying must be conducted simultaneously with the photographing, either by having the eyepiece on the telescope, or, better still, by having a proper arrangement of lenses to throw a magnified moon image at once on the collodion" (Roy. Soc. Proc., vol. viii. p. 363, 1857).

In 1857, Mr. S. Fry obtained photographs of the full moon by means of an eight and a half inch refractor. With this instrument it was found that the average exposure for the full moon was three seconds, for half moon twelve seconds, and for quarter moon forty-five seconds; collodion plates being used. Mr. Fry observed that the distance of the chemical focus from the object-glass was subject to variation, the change being most probably due to variations in temperature (*Photographic Journal*, vii. p. 80, 1862).

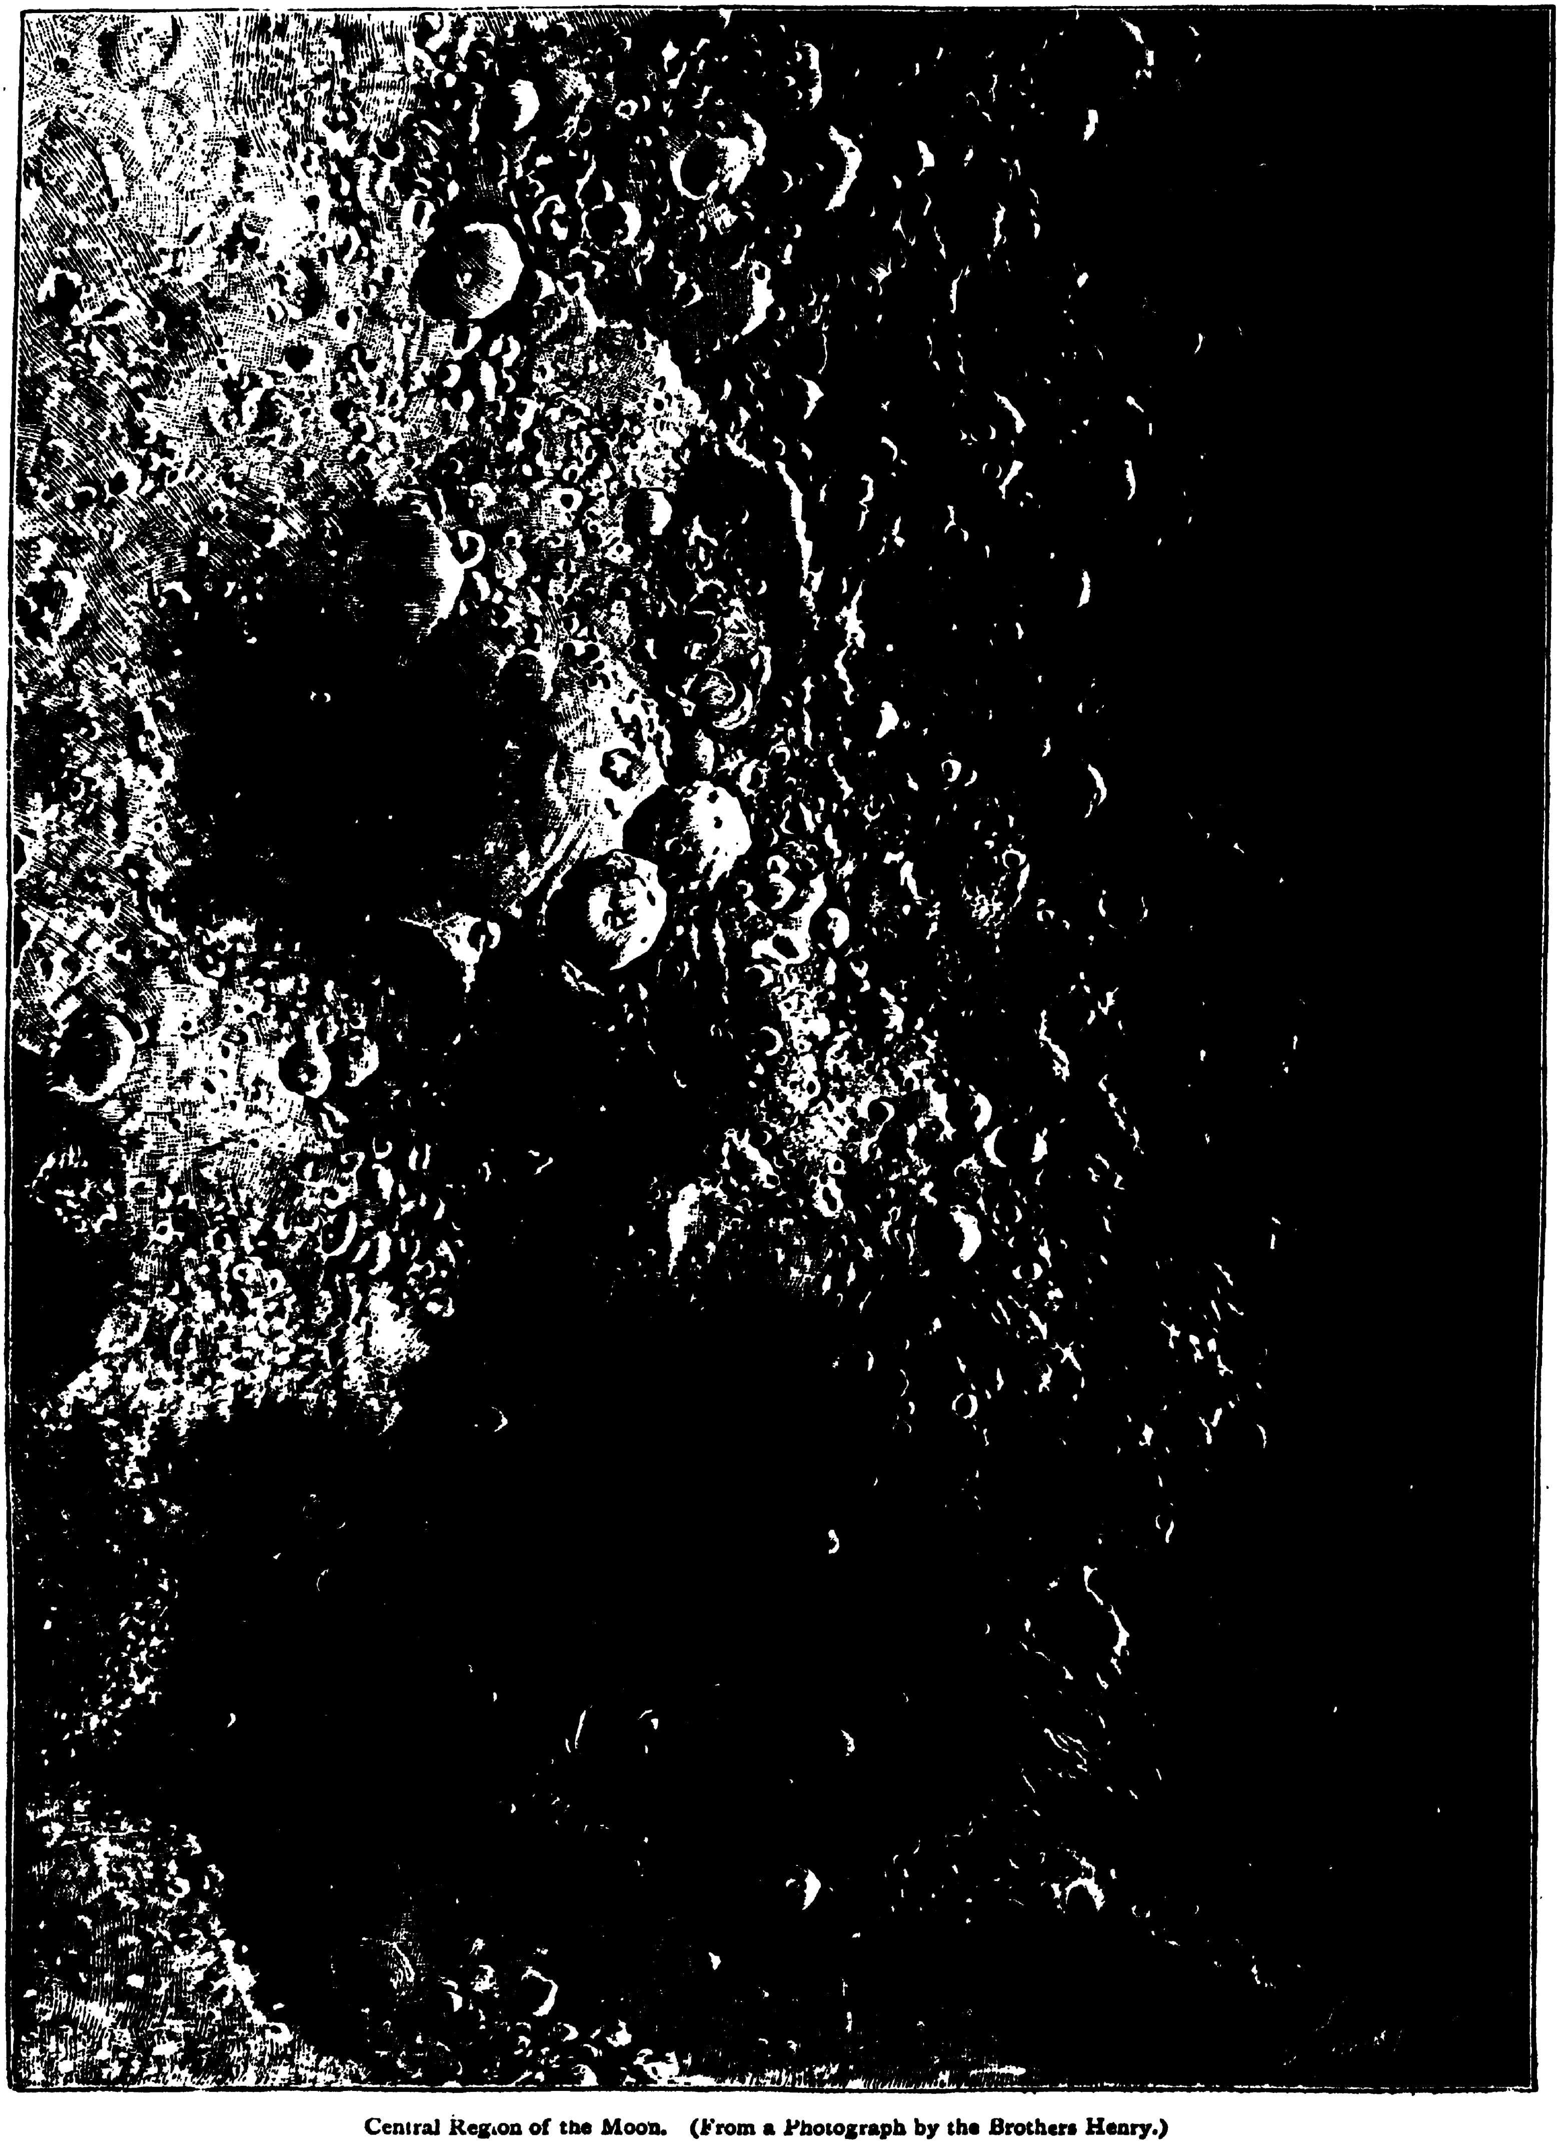
Secchi paid much attention to the photography of particular portions of our satellite, and during the first quarter. The chemical activity of the light of the moon at full and at first quarter was found to be in the proportion of three to one (*Comptes rendus*, vols. xlii., xlvi., 1856, 1858). In 1857, Sir Howard Grubb, using a refractor of 12 inches aperture, obtained photographic images of the moon a little over two inches in diameter with exposures from ten to forty seconds. A sliding back similar to that invented by De La Rue and afterwards improved upon by Lord Rosse, was used to follow the moon's motion. The improvement consisted in the application of clock-work motion to the slide in order to follow motion in declination and in regulating the driving clock of the equatorial to follow the moon in right ascension (Dublin Photographic Society, May 6, 1857.)

Although De La Rue obtained some excellent photographs in 1852, when working under very disadvantageous conditions, it was not until 1857 that he began to produce those detailed representations of the lunar surface that have made his name immortal. The want of a driving clock was the cause of the cessation of lunar photography in the former year, and when this had been supplied, De La Rue continued his work. Numerous positives on glass and negatives slightly more than an inch in diameter were obtained. These were perfectly defined and bore a magnification of more than 16 diameters. In 1859, at the British Association meeting held at Aberdeen, De La Rue reported "On the Present State of Celestial Photography in England," and exhibited some of the fruits of his labour. Amongst the specimens were positive enlarged copies of other negatives, eight inches in diameter, which would bear still further enlargement, and instantaneous pictures of the full moon. It was noted that very strong pictures of the full moon were produced with exposures from one to five seconds, and that the crescent moon required from twenty to thirty seconds. A great part of the report was devoted to a discussion of the methods adopted in taking stereoscopic pictures of the moon, many photographs of this character being exhibited at the meeting.

The extensive multiplication of enlarged copies of De La Rue's negatives renders it unnecessary to expatiate on their excellency. A magnificent series of twelve photos was published in book form, and also enlarged so that the lunar disk had a diameter of seventeen inches. In this series the moon's progress was traced from the time when she was six days old through the waxing and waning periods to the 23½ day. Each of the pictures was a work of art, whilst the many details they contained gave them a high scientific value, and conclusively demonstrated the applicability of photography to the delineation of celestial bodies.

An enlargement three feet in diameter, from a negative taken by De La Rue in 1858 is suspended in the library of the Royal Astronomical Society.

Rutherford began his work in lunar photography in 1858 with a refractor having a focal length of fourteen feet, and an aperture of eleven and a quarter inches. By reducing the aperture of the telescope to five inches for the full moon, negatives were produced which would bear enlargement to fifty diameters, or five inches. In the same year, whilst De La Rue was obtaining stereoscopic pictures in England, Rutherford was working in the same direction in America, and with similar results. To the general public the photographs taken by Rutherford in 1858 left little to be desired, but they did not reach that degree of perfection which is necessary to satisfy a scientifically cultured mind. A mirror having a diameter of thirteen inches was, therefore worked and fixed on the tube of the refractor in 1861. The results obtained were, however, still deemed unsatisfactory. The mirror soon became tarnished by the action of the combustion products of the gas used for illuminating purposes, while the motion of vehicles in the



Central Region of the Moon. (From a Photograph by the Brothers Henry.)

neighbouring street gave it vibrations, which by reflection were doubled in amount. The reflector was therefore abandoned, and Rutherford resolved to have an object-glass made of the same size as that formerly used by him, but specially corrected for photographic rays. With the completion of this instrument Rutherford's best results began. In March 1866, some remarkably fine negatives were obtained with exposures from two to three seconds three days after the first quarter, and one-quarter of a second for the full moon. The publication of enlargements from these negatives, having a diameter of twenty-one inches, was much appreciated by astronomers and others interested in lunar photography.

No man has done more in the furtherance of celestial photography than Dr. Henry Draper, the son of the renowned physicist to whom reference has already been made. After a brilliant scholastic career he was associated with his father in many important researches. A journey to the British Isles in 1857 gave Dr. Draper the opportunity of visiting Lord Rosse's observatory at Parsonstown. He was so struck with the power of the great reflecting telescope, that on returning to America in 1858 he began the working of a similar speculum having a diameter of 15 inches. This was afterwards discarded, and a silvered glass Newtonian reflector, having a diameter of 15½ inches, was constructed, and adapted for celestial photography. Detailed descriptions of the construction and testing of the mirror, the method of silvering, and the manner in which it is mounted, are embodied in a memoir by Dr. Draper "On the construction and use of a silvered glass telescope, 15½ inches in aperture, and its use in celestial photography" ("Smithsonian Contributions to Knowledge," vol. xiv. p. 52, 1864). Instead of driving the telescope in the usual way by means of a clock, Dr. Draper used a sliding plate holder, driven by a "clepsydra" specially devised for the purpose. Some perfectly defined negatives were obtained in 1863, about 1½ inches in diameter; many of them were enlarged to 2 feet, and from one a magnificent picture was made in which the lunar disc had a diameter of 50 inches. The beauty of the copies was probably due to some extent to the fact that a concave mirror was used instead of a combination of lenses in the process of enlarging.

From the time when Dr. Henry Draper produced his best results until last year very little remarkable work had been done in lunar photography. In 1866, Mr. A. Brothers took several good negatives 1⁄16 of an inch in diameter in the first focus of a 5-inch refractor, and by the insertion of a Barlow lens he increased the size of the image to 1¼ inches. Enlargements from these negatives were distributed to many astronomers, and evidence of their excellency is afforded by the circumstance that they were mistaken for some of Rutherford's productions by the editor of a scientific journal, and commented upon as such. Mr. Brothers gave a long account of the development of celestial photography in the paper in which his method of work was described (Proceedings of the Literary and Philosophical Society of Manchester, vol. v. p. 68, 1865-66.)

In 1872, Mr. Ellery, the Director of Melbourne Observatory, presented some remarkably sharp lunar photographs to the Royal Astronomical Society, that he had obtained by means of the great reflector (*Monthly Notices R.A.S.*, vol. xxxiii. p. 219, 1873.)

Amongst other lunar photographs possessed by the Royal Astronomical Society are two taken by Dr. Gould at Cordoba Observatory in 1875-76, in each of which the moon has a diameter of nearly 20 inches. A photograph taken in 1877 by Prof. Pritchard at Oxford, with the reflector used by De La Rue, and some taken in 1880 by Mr. Common with his three-foot reflector, also figure in the above collection as remarkable works of art having an important scientific signification.

In a recently published paper on "Astronomical Photography at the Lick Observatory" ("Publications of the Astronomical Society of the Pacific," vol. ii., No. 9), Prof. Holden gives a detailed account of the photographic apparatus of the great equatorial, and the work done with it. The image of the moon in the first focus of this instrument is nearly five and a quarter inches in diameter, and the negatives bear easily an enlargement of 570 diameters, and even double this amount. In the production of these negatives the aperture of the object-glass was reduced to 12 inches. From an examination of the best pictures yet taken at the Lick Observatory, Prof. Holden finds that parallel walls on the moon whose tops are no more than 200 yards or so in width, and which are not more than 1000 or 1200 yards apart, are plainly visible. A series of copies from the negatives obtained at Lick Observatory has been published.

Some photographs of the moon taken in March last, by the Brothers Henry, at Paris Observatory, appear to eclipse all previous ones. The instrument used was the 13-inch photographic equatorial, and an examination of the plate which accompanies this note will show that real progress has been made. The superiority of the results is due not only to the perfection of the object-glass, but to the use of a secondary magnifier, by means of which the size of the image at the first focus was increased fifteen times. It is manifest that this method of direct enlargement possesses many advantages over that ordinarily used, and its further development will be awaited with considerable interest.

There is no doubt that enlarged photographs of our satellite are capable of affording more information regarding its surface than can be gained by years of diligent observation, whilst their multiplication at different epochs will enable selenographers to readily detect changes of a comparatively minute character. The study of the lunar surface has always excited interest. Hence the contribution to knowledge afforded by the photographs taken by MM. Paul and Prosper Henry will not lack the appreciation it fully deserves.

RICHARD A. GREGORY.

COMPARATIVE PALATABILITY OF INSECTS, &c.

In the course of last autumn and the present summer we made a series of experiments bearing upon the relative palatability of insects, &c.,; the animals chiefly experimented on being domestic mice, common toads, and a common Mynah (*Acridotheres tristis*). We obtained the following results.

Among beetles, *Carabus violaceus*, which emits a very strong, unpleasant-smelling fluid, was once eaten by the toads, and twice by the mice. As a rule, however, it seemed too large and strong for either. The Mynah, also, was not very fond of it.

Torostichus niger, and the nearly-allied red-legged species, which also emit strong-smelling fluid, were readily taken by all the animals under observation: though they sometimes caused the mice a little trouble.

The small copper-coloured ground-beetles were eaten readily by the Mynah and toads, but in every case refused by the mice.

Melolontha vulgaris was liked by the mice and toads. We did not offer it to the Mynah.

Coccinella bipunctata was invariably licked and refused by the mice, even when hungry. The toads took it readily. We did not offer it to the Mynah.

Ocypus olens, the "devil's coach horse," was taken without hesitation by the toads, even in its defiant attitude, with the head and abdomen erected. On one or two occasions, however, it was immediately ejected. This has also happened with *Torostichus niger*, and appears

to be due to the bite of the insect rather than to the emission by it of unpleasant matter. The *Ocypus* was eaten by the Mynah.

The red soldier-beetle was seized by one mouse, which, however, left the abdomen. It was refused by another, which was feeding rather poorly at the time; though the same animal, immediately afterwards, killed and partly ate a house-fly. This beetle was eaten by the toads. We did not offer it to the Mynah.

The dung-beetle (*Geotropes stercorarius*) was offered only to the toads. It was apparently too large and strong for them.

Among Hymenoptera, only one *Bombus* (*terrestris*) was offered to the mice: they seemed afraid to touch it. We were surprised at this, in the face of Darwin's fact of field-mice attacking nests of Bombi. The Mynah ate wasps greedily. The toads readily took wasps and bees (*Megachile*, *Apis*, *Bombus*), only occasionally refusing the large queens of the Bombi. They were often stung, but did not seem to suffer from this, since they would take three or four of the insects in succession.

We were not fortunate enough this year to take any of the Chrysididæ. Experiments should certainly be made with these.

Of Lepidoptera, the Mynah was offered *Pieris rapæ* and *Vanessa urticæ*. It would eat both; but greatly preferred the latter. We gave the mice *Pierides rapæ* and *napi*, *Vanessa urticæ*, *Tryphæna pronuba*, some other (dull-coloured) *Noctuæ*, and some *Geometræ*. All were eaten. *Pieris rapæ*, *Vanessa urticæ*, *Bryophila perla*, *Plusia gamma*, and several other (dull-coloured) moths, were offered to the toads. Two specimens of the *Bryophila* were eaten; but the other insects were almost invariably unregarded. This appeared to us to require explanation, as the other animals ate butterflies and moths so readily. We kept our toads in an open enclosure; and were therefore obliged to mutilate the wings of the insects given them. The consequence was that these either fluttered violently or remained perfectly stationary; and toads do not seem to take food under either of these conditions.

The silkworm moth was taken by the mice; to which alone we offered it.

The swallow-tail moth (*Urapteryx sambucaria*), of which we only obtained one specimen, was eaten by a mouse.

Green and brown larvæ were taken greedily by the Mynah and toads. The latter also ate the bright-coloured caterpillars of *Pieris* sp. (*rapæ?*), and any hairy caterpillars that were offered them. Among them was that of *Orgyia antiqua*. In one case a hairy caterpillar was not swallowed till two or three attempts had been made to secure it. No hairy caterpillars were offered to the other animals.

Some bright orange-coloured larvæ, with black heads—found feeding, in a web, on hawthorn—were readily eaten by the toads and by one mouse. Another mouse (feeding poorly) refused them.

A scarlet-and-black bug was eaten by the toads; as also was the lace-wing fly (*Chrysopa perla*). Neither insect was offered to the other animals.

Three sword-tailed grasshoppers were readily eaten by a mouse.

Blatta orientalis was eaten by the toads. We did not give it to the mice. The Mynah for a long time refused it, and only took it finally in the dearth of other insects. The same holds good, in its case, of *Lumbricus terrestris*.

A few centipedes were given to the mice and the Mynah. These were never eaten; though the mice, in one case, eagerly seized and killed a large specimen. We offered small frogs to the Mynah, which seized, but did not eat them; leaving them apparently unhurt. The toads eat—though with some difficulty—small newts; which a water tortoise (*Emys* sp.) will not take.

E. B. Titchener.
F. Finn.

A young heron (*Ardea cinerea*), which takes frogs freely, killed, but did not eat, a common toad.

A water-tortoise (*Emys* sp.), though it eats small frogs, will not touch a toad. E. B. Titchener.

Zeuzera æsculi was offered to a prairie owl at the Zoological Gardens; and though eagerly seized, left alive after considerable examination. Queen ants were taken by toads and by the common lizard (*Lacerta vivipara*).

F. Finn.

THE PROGRESS OF BIOLOGY IN CANADA.

We have before us the official account of the formal opening of the new building of the Biological Department of the University of Toronto, on December 19 last. The building is a substantial stone one in Scottish Norman style, replete with the most modern fittings and accessories; and the lecture hall, which may be approached independently of the main edifice, is benched to seat a minimum audience of 250. The work of the institution is presided over by Prof. R. Ramsay Wright. The classes in biology are said to be among the largest in the University, and the excellence of the new arrangements and teaching appliances elicited, at the opening ceremony (from Prof. Osler, an old student of the parent college), the remark that "it is possible for one to live through a renaissance, similar perhaps in kind, less important in degree, than that" directed against mediæval thought. May this be justified! Certain it is that the biological work now in progress in Toronto was begun under most auspicious circumstances.

Prof. Ramsay Wright is well-known and respected in this country and, at the opening of his new building, allegiance was sworn him by Minot and other biologists of the New World whose published researches, like his own, rank high in contemporary literature. Investigations like those upon the spiracular cleft of Ganoids, the nervous system of the tadpole's epiderma and of the liver, which his school has given to the world, are not to be easily matched as thoroughgoing and honest pieces of work. They denote a high standard of attainment, and one which, in face of the inanities of certain trans-Atlantic workers of another type, must be maintained if the biological brotherhood of the New World is to hold its own.

The Biological Department of the University of Toronto exists in connection with a Medical School, and it is therefore not surprising to find signs of a leaning towards bacteriology and those allied branches of study which, as being furthered by Mentschnikoff and his pupils, by Darier, Podwyssozki, Neisser, Ruffer, Macallum, and others, are just now assuming a revolutionary phase. Indeed, the key-note was struck by Prof. Wright in the peroration to his opening address, in which he said that "not only bacteria, but low forms of animal life furnish important pathogenic organisms." We rejoice in this the more, now that an outcry against the biological training of the surgeon-student is being raised at home, by persons who clamour for the restoration of an apprenticeship system. From the utterances of distinguished medical experts made at the Toronto ceremony, it is certain that this proposal will meet with no response from the New World.

The Biological Institute of Toronto is detached from the main University building. The latter was, on February 14 last, almost wholly destroyed by fire. During the preparations for the annual *conversazione*, a wooden

tray covered with lighted lamps fell to pieces, while being carried; a lamp was upset, and, although the burning mass was heroically carried towards the exterior by the Sub-Curator and a caretaker, the building, its valuable contents, museums, and books, were for the most part destroyed. Prof. Wright has been for some months on a tour of inspection in Europe, seeking, among other things, gifts of specimens and books. Truly, our Canadian brethren do not deserve these unless better able to take care of them than in the past. Prof. Wright assures us that such will be the case, and, on his behalf, we appeal to specialists and others who may be possessed of duplicates, and to those who may be otherwise willing, to help. The position is one which threatens to injure seriously the educational prospects of a rapidly advancing country to which we, at home, are much beholden; and it calls for combined action, by which alone a loss such as that we deplore can be made good.

NOTES.

AT a meeting of the Royal Geographical Society of Australasia, held at Melbourne on August 22, a letter from Sir Thomas Elder was read, in which he offered to bear the entire cost of an expedition to the unexplored regions of Australia. A report on the question of Antarctic exploration was also submitted to the meeting. In this report it was stated that public interest in the subject had been revived by the announcement that Baron A. E. Nordenskiöld, after a conference with his friend, Baron Oscar Dickson, had consented to take the command of an expedition to the South Polar regions, on the condition that the Australian colonies contributed a sum of £5000 towards the expenses, Baron Dickson having offered to advance the other moiety, or whatever more might be necessary. "The offers were cordially accepted, and the Antarctic Committee felt itself justified in making the necessary arrangements without delay for collecting the amount to be contributed by the Australasian colonies. The Council of the Society had passed resolutions recognizing a national duty in the exploration of the Antarctic regions, especially that portion lying opposite to Australasia, pledging itself to use its influence in promoting the enterprise, and giving authority to head a subscription list in aid of the Swedish-Australian Exploration Fund with a donation of £200 from the Society's funds. It would appear from the hearty reception accorded to the proposals of the Antarctic Committee that the latter might rely upon the energetic co-operation of all the scientific societies of Australasia, and thus be enabled to collect the amount of the contribution promised towards defraying the expenses of the combined Swedish and Australian Exploring Expedition to the South Polar Regions." The report on being put to the meeting was "received with acclamation."

AN expedition to Greenland will start from Denmark next year, under the command of Lieutenant Ryder, to investigate the east coast between lat. 66° and 73°.

PROF. EDWARD HULL, F.R.S., has severed his connection with the Geological Survey of Ireland, of which he has been Director for nearly 21 years. The one-inch geological survey of Ireland having been completed, the staff has been reduced. The Dublin *Daily Express*, commenting on Prof. Hull's retirement, says he takes with him "the best wishes of his colleagues, who will retain a vivid recollection of the consideration, kindness, and sympathy which he ever manifested towards them."

THE India Store Department lately sent to the Royal Gardens, Kew, specimens of oak-staves which had formed part of a beer-barrel. The barrel was made in the early part of 1889, filled with malt liquor in the autumn, and shipped with others as Government stores in March 1890 to Calcutta. The contents were spoiled, and the authorities at Calcutta reported that some casks were found to have been attacked by wire-worm or borer. Were the casks unsound when shipped from this country, or had they been attacked on board ship during the voyage out? The matter was submitted to Mr. W. F. H. Blandford, Lecturer on Entomology at the Indian Civil Engineering College, Cooper's Hill; and his report, which embodies the results of much ingenious labour, is published in the new number of the *Kew Bulletin*. "Notwithstanding the somewhat scanty material that was available," says the *Bulletin*, "Mr. Blandford has very skilfully traced the cause of the injury, and probably also identified the particular insect concerned. Further, he has shown that the injury to the wood had occurred before it was worked up into barrels, although, owing to the very minute holes made by the insects, it was almost impossible to detect their presence." Other subjects dealt with in this number of the *Bulletin* are: prickly pear in South Africa, Jarrah timber, treatment of mildew on vines, cultural industries in West Africa, and economic plants of Madagascar.

MR. CECIL CARUS-WILSON writes to us that he has recently invented a luminous crayon for the purpose of enabling lecturers to draw on the blackboard when the room is darkened for the use of the lantern. He hopes that the invention may prove of value not only to lecturers who use a lantern, but also (in another form) to those students who wish to take notes.

MR. ROBERT SWORDY, of Dryburn Cottage, Durham, sends us a letter which has been printed in the *Durham County Advertiser*, giving an account of a toad (*Bufo vulgaris*) which he recently saw crawling out of the Pond Wood at Aykleyheads. The muscles of the toad's body were (as usual) arranged in such a fashion that the back of the toad looked like minute nodules of dark gravel embedded in a damp path below trees; but what seemed to Mr. Swordy most remarkable was that on the top of this gravel-like arrangement of muscles there was spread a mesh or network of very fine lichen, with oval-shaped leaves of a lightish green colour, connected more or less to each other by a hair-like process of stems. This lichen spread irregularly over the toad's back, and odd sprays of it were also to be seen on the legs and upper surfaces of the feet. "Now," says the writer, "had the toad been in its regular haunts under the trees and shrubs, with this wonderful counterfeit of gravel and protective colouring, it would have been almost impossible to discriminate its form from the dark gravel, lichens, moss, wood-sorrel, and dead leaves of the place, and I doubt not that this animal's unobtrusive attire would aid it materially in capturing the insects necessary for its sustenance." Mr. Swordy encloses photographs of the toad sitting on a section of lichen-coloured gravel path, taken from near the spot where he found it.

MESSRS. THOS. J. SYER AND CO. inform us that they have, at 45 Wilson Street, Finsbury Square, London, a class-room in which are taught, practically, various trades, such as carpentry, cabinet-work, wood-carving, &c. The winter session is said to have been very successfully opened, and Mr. Syer, who acts as principal, invites anyone who may be interested in the subject to visit the room, and see the work in progress.

A WORK on art among the Dayaks of Borneo, by Alois Raimund Hein, has been issued at Vienna. The publisher is Alfred Hölder.

MR. WILLIAM P. COLLINS, scientific bookseller, has issued a Catalogue (No. 24) of miscellaneous scientific books.

THE next meeting of the Royal Microscopical Society will be held on Wednesday, the 15th inst., at 8 o'clock, when the following papers will be read:—Note on a new type of Foraminifer, by H. B. Brady; new method of demonstrating intercellular protoplasmic continuity, by P. C. Waite; and, simple form of warm stage for the microscope, by F. Dowdeswell.

THERE is some difference of opinion as to the original meaning of the word "kangaroo." At the meeting of the Linnean Society of New South Wales on August 27, the question was discussed whether, in the dialect of the blacks of the Endeavour River, the word signified "I don't know," and was so used in answer to the queries of Captain Cook's party, or whether, as Cook supposed, it really was the name of the animal in use among the aborigines of the locality.

AT the same meeting Mr. A. J. North criticized the statement of the late Mr. Gould that the gay attire of the members of the genus *Malurus* "is only assumed during the pairing season, and is retained for a very short period, after which the sexes are alike in colouring" ("Hand-book to the Birds of Australia," i. 317). According to Mr. North, full-plumaged males, more particularly in the section of the genus in which blue predominates, are to be met with all the year round.

A VALUABLE contribution to the subject of atmospheric electricity has been lately made by Prof. L. Weber, who, in experiments at Breslau, used a sensitive, earth-connected galvanometer, instead of the electroscope in Exner's method. Using Exner's metallic rod and flame, he found that the currents were extremely small, about a micromilliampere (or the thousand-millionth part of an ampere). They were increased with a longer rod and bigger flame; but much better results were got with a kite or captive balloon. The edge of the kite was coated with silver paper, and the tail was formed with tassels of the paper. A line of fine steel wire was used, and about 12 feet at the upper end were of non-conducting string. Experiments were made on 12 cloudless days. Taking the intensities of current as ordinates, and the heights to which the kite (or balloon) rose as abscissæ, the curve of intensity had its convex side to the axis of abscissæ. On but few days was the current negative, this effect being probably due (the author thinks) to dust charged with negative electricity which it gave to the line. This might neutralize some of the positive electricity set flowing in the wire by the earth's induction. Prof. Weber considers that any experiments on the earth's surface with short conductors can at best give relative values and determine periodical changes. His values differ not inconsiderably from Exner's. At a height of 350 m. (1166 feet) the potential was found to be 96,400 volts; and, assuming a regular increase of potential with height, the fall of potential would here be 275 volts. The potential of the earth is estimated at the enormous value of $1720 \cdot 10^6$ volts. Supposing the volt to be about the electromotive force of a Daniell element, a huge battery of this number of elements would be needed to produce the earth's potential, the zinc pole being connected with earth, and the copper led into space. Prof. Weber considers the question of possible electric repulsion from the earth, and is led to some instructive remarks on rain particles, clouds, &c. Some very interesting effects were obtained from thunder-clouds; but for these and other matters we may refer to the original (an account of these researches appears in *Humboldt* for September).

THE Smithsonian Institution is publishing some interesting reports of the results of explorations by the U.S. Fish Commission steamer *Albatross*. In one of these reports Mr. Charles H. Townsend deals with birds from the coasts of western North America, and adjacent islands. Mr. Townsend, referring to several of the islands visited by the *Albatross*, points out that a rich field awaits the naturalist who may explore them. "The islands of the Santa Barbara group," he says, "have hitherto been very imperfectly explored with regard to their fauna. Clarion and San Benedicte Islands, of the Revillagigedo group, had never before been visited by naturalists. Socorro, an island of the same group, and one abounding in peculiar species of vertebrates, had not been visited since the type specimens were collected by Grayson, about the year 1870. The flora of all the Revillagigedo Islands is practically unknown, as the *Albatross* brought back only a small collection of flowering plants."

THE Royal Meteorological Society have published the first part of vol. x. of the *Meteorological Record*, containing the results of observations for the quarter ending March 31 last, with remarks on the weather by W. Marriott, Assistant Secretary, containing a large amount of useful information, compressed into 20 pages. The remarks show at a glance whether temperature, rainfall, &c., have been above or below the average; for the period in question the temperature of January was, on the whole, very mild, while cold spells occurred from February 3–15, and from February 20 till March 5. During the first few days of March, temperatures were lower than in any other March for nearly 50 years; but, on the whole, the temperature of the quarter, and also the rainfall, were above the average. The tables contain the values of bright sunshine for 31 stations; monthly results of observations at stations of the second order (for 9 a.m. and 9 p.m.) at 25 stations; abstracts of climatological observations, chiefly temperature and rainfall (for 9 a.m.) at 73 stations; earth temperatures observed between 3 inches and 6 feet at various stations; and, lastly, the observations from the Quarterly Reports of the Registrar-General, with remarks on the weather by James Glaisher.

THE second part of the Annual Report of the Chief Signal Officer (U.S.) for 1889 contains a treatise entitled, "Preparatory Studies for Deductive Methods in Storm and Weather Predictions," by Prof. Cleveland Abbe. The object of the paper is to consider the physical principles that are involved in the formation and motion of storms, and that have guided the author in predicting storms in his official capacity in the Signal Service, and it is an able and most instructive exposition, with very few mathematical formulæ, of the progress made in meteorological science during the last thirty years. The author distinguishes between matters that are important, such as the earth's rotation, gravitation, and solar radiation, and those that are unimportant, such as lunar influence, atmospheric electricity, and magnetic disturbances. The general idea that underlies the work is that a storm centre moves towards the region where conditions produce the greatest precipitation of aqueous vapour. Objection is urged against the idea that high westerly currents carry the storms of America eastward. The work is obtainable in a separate form.

A NEW theory of sea-sickness has been recently offered by M. Rochet. Accepting the view that the symptoms are those of cerebral anæmia, he accounts for this anæmia by the disorder brought into muscular contractions through not being used to such sudden movements as those of vessels. He points out the enormous capacity of the reservoir formed by the muscular and perimuscular venous system, and the considerable *rôle* of tonicity and voluntary or reflex muscular contractions in the action of emptying it; also the predominance of reflex muscular actions over voluntary, in keeping one's balance, and in most movements. In the movements of a vessel, the relaxation of muscular tonicity and suppression of reflex movements result in a considerable increase of the peripheric reservoir, and, as a consequence, in cerebral anæmia. Hence it is that the descent of the ship is the most trying motion; and one can understand the benefit of the horizontal position, compression of the abdomen, fixing the body in a tight position, &c. Very young children are not ill, because the education of the reflexes in them is not yet accomplished. On solid ground they reel as on deck. M. Rochet's advice is, not to look to anæsthetics, soothing drugs, &c., for relief, but rather to muscular excitants, and above all to seek in voluntary movements a compensation for the reflex.

movements which are not produced. He recommends strychnine, veratrine, ergot of rye, and drinks charged with carbonic acid.

MR. S. V. PROUDFIT has presented to the U.S. National Museum a collection of stone implements from the district of Columbia. In an account of the collection, published in the Proceedings of the Museum, Mr. Proudfit pays a tribute to the handicraft of the aboriginal tribes of the region in which the collection has been formed. The material with which they wrought was, he says, the most obdurate and refractory of all substances found available to any considerable degree among the American Indians. Quartz, quartzite, and argillite for the greater part were used from necessity, no better material being within reach. The first two are very hard, and, in the hand of the workman, full of unpleasant surprises. The argillite, though softer, is not susceptible of receiving or retaining any high degree of finish. Notwithstanding these obstacles, the material was treated "with such patience, care, and skill, that the work of this region, not only in matters of utility, but in points of finish, compares favourably with that of any other."

A PAMPHLET by Dr. Edward Sang, on the exhibition of curves produced by the vibration of straight wires, which was read before the Scottish Society of Arts last November, has been sent to us. The means adopted for obtaining these curves was to make one end of a wire fast in a vice, while the other end was free to move; the motion of the wire being made visible by fixing to the free end a small polished knob capable of reflecting light from some given source. These phenomena were clearly found to be connected with the unroundness of the wires, and the object of the paper was to inquire what would be the result with a given irregularity. The ratios of vibrations having been varied, different results were obtained, and it was noted that when the ratio was expressed by two odd numbers, the closed curve connected two opposite corners and passed through the centre, but that when one of the numbers was even, the closed curve connected two adjacent corners and did not pass through the point of rest. Illustrations of some of these curves are given, showing their delicacy and symmetry similar to those curves formed by the resultant motion of two pendulums of different periods oscillating at right angles to one another. With bent wires particularly, as the author states, "the poetry of motion, the gracefulness of curvature, attract the student of the fine arts, who may find examples ranging from the severe classic and tragic to the extravagant burlesque styles."

IN the last issue of the *Bulletin* of the Moscow Naturalist, Madame Marie Pavloff concludes her excellent studies on the palæontology of the Ungulata. She examines the fossil relics of the *Hipparion* in Russia (*H. mediterraneum* and *H. gracile* which she considers as the same species, and the probably new species of *H. minus*), as well as the relics of the Pleistocene horses found in Russia, and gives a genealogy of the Equideæ since the Mio-Pliocene period. At the beginning of the Middle Pliocene, horses akin to *Eq. hippidium*, which at that time were living in America only, emigrated from West America to Asia, and during the Middle Pliocene epoch they developed in the Siwalik mountains into forms now described under the name of *Equus sivalensis*. Part of the latter migrated from Asia to Africa, at that time connected with Italy, and thus reached Europe. In the Upper Pliocene deposits of Africa and Europe we have the *Eq. stenonis*, which is very near to the foregoing. Having thus reached Europe from Asia during the Upper Pliocene, they left their fossil relics in the *Eq. stenonis* in Italy, Austria, Germany, France, Great Britain, and Russia, and slowly evolved the Pleistocene species of *Equus caballus*. However, one part only of the *Equus sivalensis* having left Asia, the remainder developed at the same time into the *Equus nomadicus* in Asia; while in America a parallel evolution gave rise to the *Eq. excellus* and *Eq. major* and to *Equus caballus fossilis* in Africa. As to the present horses of Russia, they all originated from the same Pleistocene species which already at that time offered great varieties in Europe. The variety of the Russian races depends upon the continued mixture of forms which developed in Russia with those which were imported from Asia on the one side, and from Western Europe on the other side.

SIR WILLIAM GREGORY, a former Governor of Ceylon, has lately been revisiting that island, and has communicated to a local journal a series of notes and observations. In one of these he refers to the well-known Colombo Museum, as to which he says it is hoped that a very liberal extension will be conceded by the Legislative Council without delay. Important objects of natural history have been procured and cannot yet be exhibited, books of value to the general reader and to inquirers have accumulated without the means of arrangement, and the space for large archæological objects which should be carefully and liberally displayed is altogether defective. There is one department, continues Sir William, hitherto much neglected, to which special care should hereafter be devoted, viz. that of geology. A geologist of high attainments ought to be engaged for a fixed period of a few years, during which a general geological survey should be made and a perfect collection be formed of the rocks, clays, and gems which are a specialty of Ceylon. These, if properly exhibited and properly protected from theft, would be one of the most valuable and interesting portions of the Museum to a large number of visitors.

THE *North China Herald* of Shanghai, in a recent curious and interesting article on modern science in China, says that the views now held by intelligent Chinese on the origin of science are that the knowledge possessed by their ancestors leaked out to the men of Western nations, who improved on the information they received, and gradually developed modern sciences and inventions. This idea was started by Mei Wu-ngan in the reign of Kanghi, and has been maintained ever since with singular persistence, and the cultivated class have consoled themselves with this thought during the past two centuries. Those who are really in favour of introducing foreign improvements say:—"We wish to make use of the knowledge of Western men because we know that what they have attained in science and invention has been through the help that our sages gave them. We have a good right to it. What Europe has done she has done through the help we gave. If we did not exactly give science to Europe, we gave it the fruitful germ which produced it. They have the science of optics, but in our 'Motsz' we find that reflection from mirrors was known in the days of Mencius. The men of the West hold that the earth is round. This was believed also by our poet Chü Yuen, who in his ode on astronomy announces this doctrine; and this was not many years after Mencius. This being so, we ought not to be ashamed of the study of Western science. We are the rivals of the Western kingdoms, and it is good policy to use their spears in order to pierce their shields. We ought to train our youth in Western science so that we may know how best to meet them in the struggle to resist their encroachments." Mei Wu-ngan and others read the books translated by the Jesuits, including Euclid and the teaching of astronomy, and they were delighted with the new views. The Jesuits, however, were in high favour at Court, and while they basked in sunshine the native mathematicians shivered in the shade. This was not agreeable, and the native astronomers went home each day from Court dissatisfied. One of them, Yang, ventured to foretell an eclipse. Adam Schaal, a Jesuit, in Pekin, foretold the same eclipse, and his hours, minutes, and seconds agreed with the fact. This was a crucial case. All Pekin was waiting with interest to know the result. The pro-

phecy of the foreigner proved by its fulfilment the errors of the Chinese mathematician, who retired in disgrace from the position which he held. He went back to his home to write the book called "The Inevitable Exposure," which contained a series of calumnies and grossly untrue accusations against the Jesuit fathers. This bad book made him much more notorious than his works on mathematics. The unscrupulous enemies of the Westerns have reprinted it again and again, and they still do so. Very different was the tone of Mei Wu-ngan, who was invited three days in succession by the Emperor Kanghi to converse with him upon mathematical subjects. He had a fondness for mathematics, and read voraciously. He was therefore in a position to criticize Western knowledge in an appreciative manner.

The additions to the Zoological Society's Gardens during the past week include two Grizzly Bears (*Ursus horribilis*) from the Missouri Brakes, Montana, U.S.A., presented by Mr. Ewen Somerlid Cameron; a Raccoon (*Procyon lotor*) from the Catskill Mountains, New York State, presented by Mr. James H. Frodsham; a Greater Black-backed Gull (*Larus marinus*), a Herring Gull (*Larus argentatus*), British, presented by Mr. A M. Bailey; a Common Tern (*Sterna hirundo*), British, presented by Mr. A. C. Howard; two Mississippi Alligators (*Alligator mississippiensis*) from the Mississippi, presented by Miss Edith Baker; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, a Great Kangaroo (*Macropus giganteus* ♂) from Australia, deposited; a Horned Screamer (*Palamedea cornuta*) from the Amazons, three Violet Tanagers (*Euphonia violacea*) from Brazil, an Ocellated Sand Skink (*Seps ocellata*), South European, purchased; a Chestnut-breasted Duck (*Anas castanea*) from Australia, received in exchange; a Crested Pigeon (*Ocyphaps lophotes*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

Objects for the Spectroscope.

Sidereal Time at Greenwich at 10 p.m. on October 9 = 23h. 13m. 52s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 4892	—	—	22 59 26	+11 44
(2) G.C. 4921	—	—	23 10 22	+ 5 46
(3) χ Aquarii...	5	Yellowish-red.	23 11 9	− 8 13
(4) ξ Pegasi	5	Yellowish-white.	22 40 26	+11 40
(5) 19 Piscium	6	Red.	23 40 46	+ 2 52
(6) R Aquilæ	Var.	Very red.	19 1 5	+ 8 4

Remarks.

(1 and 2) Neither of these nebulæ have yet had their spectra recorded. The first of them is about 4′ long by 2′ broad, and has been described as "a streak tapering at each end"; in the General Catalogue it is described as "pretty bright; considerably large; much elongated in the direction 11°·9; between two stars." The second is described as "considerably bright; pretty small; irregularly round; pretty suddenly brighter in the middle." They are both very conveniently situated for observation.

(3) The spectrum of this star is a very fine one of Group II., all the bands being wide and dark. Carbon comparisons will probably be the most valuable observations of this star, the character of the spectrum indicating that the flutings should be considerably bright.

(4) Secchi thought that this star had a banded spectrum, but Dunér states that it is one of the solar type ("Sp. II.*a* ! du type le plus pur"). It still requires observing with reference to Groups III. and V.

(5) The spectrum of this star is one of the very finest of its class (Group VI.). It has been observed in considerable detail by Vogel and Dunér. All the principal and secondary bands are well visible. The carbon band 6 (λ 564) is stated by Dunér to be feebler than the others, and so far as we yet know this is the only band in which any considerable variation is established. It will be remembered that this is the cometary band which varies most, but in comets it varies in position also. It seems possible, therefore, that it may also change in position as well as in intensity in stars of Group VI. Comparisons with a spirit-lamp flame would easily decide this point.

(6) This variable has a well-marked spectrum of Group II. Dunér describes it as "very fine," and states that the bands are very wide and dark throughout the spectrum. The period is about 345 days, and it ranges from 6·4–7·4 at maximum to 10·9–11·2 at minimum. The star falls in species 9 of the subdivision of Group II., and if it behaves like other variables with similar spectra, bright lines should appear at or about maximum. The spectrum should also be observed for brightenings of the carbon flutings. A. Fowler.

Observations of Comets.—Prof. E. E. Barnard, of Lick Observatory, contributes a note on Comets 1889 I. and II. to the *Astronomical Journal*, No. 225, and makes some suggestions as to the possibility of seeing the short-period comets at aphelion. The majority of observers neglect comets as soon as they become faint or difficult to see. Prof. Barnard has made it a point to take up comets when they have been dropped elsewhere, and to observe them as long as they can be seen. Comet 1889 I. has been observed at Lick Observatory from September 2, 1888, to August 18, 1890—that is, for very nearly two years; and Comet 1889 II. from March 31, 1889, to August 24, 1890—that is, for 16 months 24 days: hence the duration of visibility of each exceeds that of the great comet of 1811, which was followed for 16 months 20 days. At the observation of Comet I. 1889, on August 17, its distance from the sun was 6·25 times the earth's mean distance. On August 24, Comet II. 1889 was 5·06 times the same unit from the sun, and Prof. Barnard thinks he will be able to follow it for quite six months longer. The following are the aphelion distances of short-period comets (excepting Tuttle's) recognized at more than one return:—

Encke's	4·10	Brorsen's ...	5·66
Tempel's II. ...	4·66	D'Arrest's ...	5·72
Tempel's I. ...	4·82	Faye's ...	5·92
Swift's 1880 ...	5·14	Biela's ...	6·19
Winnecke's ...	5·50		

It will be seen that Comet I. 1889 is now being observed at a distance from the sun greater than it is possible for any of the short-period comets to attain. It would appear, therefore, that some of the latter class of comets ought to be followed throughout their entire orbits.

Photographing Stars in the Daytime.—In the *Astronomical Journal* for September 16, 1889, Prof. Holden gave an elementary theory of the subject of photographing stars projected against a bright background. He showed that, if the intrinsic brilliancy of a star be ten times as great as its background, the photographic image in the Lick telescope was 4124 times brighter than that of the sky. It was also proved that small photographic contrasts of this character could be increased with a given telescope by simply cutting down the aperture. Recently, Prof. Holden writes (*Astr. Journ.*, September 19, 1890), "the question has been examined experimentally by Mr. W. W. Campbell and myself, using the great telescope (focus, 570 inches) and apertures of 33, 15, 8, and 4 inches. Photographs of Venus, Mercury, the moon, and of Alpha Lyræ have been taken in broad daylight (2 to 5 p.m.) with the apertures named, with a constant exposure of 0·13s., and on Seed 26 plates. In general, the smallest apertures used have given the darkest images, as demanded by the theory."

PHYSICS AT THE BRITISH ASSOCIATION.

In Section A, nine Reports of Committees and fifty-four papers were read. Perhaps the distinguishing characteristic of the Section is its tendency to bifurcation on the slightest provocation. Several Sections do not meet at all on the Saturday, and manage to get through their business comfortably by the Tuesday. Not so Section A. On the Saturday, under the influence of electrolytical attractions and repulsions, there occurred a dissociation of the Section into its constituent elements, accompanied by a migration of ions from places of high potential (in a Bramwellian sense) to places of low, or *vice versâ*. In accordance with the law of ionic migration enunciated by Sir Frederick at the concluding meeting, the ions collected at the

kathode were found to far exceed in number those collected at the anode.

To give even an outline of all the voluminous and multitudinous contributions to the Section would occupy many pages, and would require that the writer should have received the training of a Succi or a Jacques before undertaking the task.

M. Du Bois read a paper on refraction and dispersion in certain metals. Kundt's method of observation with very thin electrolytic metal biprisms was used in this investigation. The dispersion was determined with all possible care, using four kinds of light defined by spectral lines. It was found that light, on passing from iron, cobalt, and nickel into air, begins by following Snell's law for small angles of emission, the refractive index being mathematically defined as the limit of the ratio of sines when the angle of incidence approaches the limit zero. The dispersion in the case of each of the three metals mentioned was found to be anomalous.

Sir William Thomson, F.R.S., in a paper on an illustration of contact electricity presented by the multicellular voltmeter, called attention to the modification of the force between the aluminium needles and the brass cells of the instrument arising from the "contact electricity" difference between polished brass and polished aluminium. In the instrument as at present made, the observed difference of potential on reversal amounts to as much as ½ volt. Thus the use of the multicellular electrometer gives a new and very interesting direct proof of Volta's contact electricity.

Lord Rayleigh, Sec.R.S., read a paper on defective colour-vision, in which he pointed out that the existence of a defect is probably most easily detected, in the first instance, by Holmgren's wool test; but this method does not decide whether the vision is truly dichromic. For this purpose, Maxwell's colour-disks may be used. Lord Rayleigh found, in the case of some colour-blind persons he was examining, that it looked as though the third colour-sensation, presumably red, was defective, but not absolutely missing. When a large amount of white was present, matches could be made, in spite of considerable difference in the red component. But when red light was nearly isolated, its distinctive character became apparent. This view was confirmed by experiments with the colour-box.

Mr. J. Swinburne, in a paper dealing with the question of the production of high vacua, called attention to the great superiority of the Geissler over the Sprengel form of mercury pump.

Profs. Barr and W. Stroud, in a paper on the use of the lantern in class-room work, described a simple and convenient form of lantern for horizontal and vertical projection, and exhibited an apparatus for the preparation of lantern-slides in large numbers from books, periodicals, &c.

Mr. W. N. Shaw read a paper on the general theory of ventilation, with some applications, in which general laws of ventilation are established similar to Kirchhoff's laws relating to the distribution of currents in a network of conductors.

On Friday, September 5, there was a discussion on electrical units, opened by Mr. Glazebrook with a paper on recent determinations of the absolute resistance of mercury, in which he carefully compared and criticised the different methods employed by various observers. The best determinations of the ohm showed that it was very nearly indeed equal to the resistance of a column of mercury 106·3 cm. long and 1 square millimetre cross-section at 0° C. Mr. Glazebrook strongly advocated the adoption of the number 106·3 instead of 106; and Sir William Thomson, Prof. Rowland, Prof. Barker, and Mr. Preece expressed their concurrence in the desirability of the change.

Principal J. V. Jones followed with a paper entitled "Suggestions towards a Determination of the Ohm," in which he described the results of experiments undertaken at University College, Cardiff, in the spring of the present year. These experiments gave the ohm equal to the resistance of a column of mercury 106·307 cm. long and 1 sq. mm. sectional area. The method adopted was a modification of that due to Lorenz, in which a metallic disk is made to rotate in the mean plane of a coaxial standard coil. Wires touching the centre and circumference of the disk are led to the ends of the resistance to be measured, and the same current is passed through this resistance and the standard coil.

The features of special interest in the method employed were:—(α) The employment of a long trough for holding the mercury; and, instead of measuring the distance between the electrodes, one electrode is kept fixed, while measurement is made of the distance moved through by the other between two positions of equilibrium of the galvanometer corresponding to two different rates of rotation of the disk. The latter measurement it is easy to make with accuracy, for the movable electrode may be rigidly attached to the movable headstock of a Whitworth measuring-machine placed parallel to the length of the trough; and the two equilibrium positions may be taken near the middle of the trough, so as to avoid danger of curvature in the equipotential surfaces passing through the electrode in its two positions. A new difficulty is, however, now encountered, viz. the determination of the section of the mercury column. The capillary depression at the sides of the trough would make it a most serious task to determine the section by direct measurements to the required degree of accuracy. This difficulty is overcome by a further differential method, viz. by making observations with the mercury at two different heights in the trough. The sides of the trough in that part of it traversed by the movable electrode are assumed plane, parallel, and vertical. The trough used in the experiments was cut in paraffin wax contained in a strong casting of iron with its sides strengthened by outside ribs. The channel was 43·5 inches long, by 1·5 inches broad, by 3 inches deep. Paraffin was found, however, not to be perfectly satisfactory, and Prof. Jones expressed the opinion that a trough of worked glass or scraped marble would have been preferable. The position of the mercury surface in the trough was determined electrically by using a pointed steel spherometer screw. The screw may be moved downwards until an electric circuit comprising the screw and the mercury is completed. (β) The employment of a brush of special form to secure good electrical contact at the periphery of the rotating disk. The brush consisted of a single wire perforated by a channel through which a constant flow of mercury might be maintained from a cistern of adjustable height. (γ) In connection with the measurements necessary to enable the calculation of the coefficient of mutual induction to be performed, Prof. Jones employs a coil consisting of only one layer of wire, the advantage of which is that every part is visible, and that nothing is done to alter the position of the wire after measurements have been made. If a coil consist of many layers, it is not quite easy to say where, after measurement, the lower layers go to under the pressure of the superincumbent ones.

In conclusion, the main suggestions offered for consideration, were:—

(1) That the time is ripe for a new determination of the ohm that shall be final for the practical purposes of the electrical engineer.

(2) That such a determination may be made by the method of Lorenz, the specific resistance of mercury being obtained directly in absolute measure by the differential method described.

(3) That the standard coil should consist of a single layer of wire, the coefficient of mutual induction being calculated by the formula given in the paper.

Sir William Thomson, in a paper on alternate currents in parallel conductors of homogeneous or heterogeneous substance, pointed out that when the period of alternation is large in comparison with 400 times the square of the greatest thickness or diameter of any of the conductors, multiplied by its magnetic permeability and divided by its electric resistivity, the current intensity is distributed through each conductor inversely as the electric resistivity; the phase of alternation of the current is the same as the phase of the electromotive force; and the current across every infinitesimal area of the cross-section is calculated, according to the electromotive force at each instant, by simple application of Ohm's law. Further, that when the period is very small compared with 400 times the square of the smallest thickness or diameter of any of the conductors, multiplied by its magnetic permeability and divided by its electric resistivity, the current is confined to an exceedingly thin surface-stratum of the conductors. The thickness of this stratum is directly as the square root of the quotient of resistivity, divided by magnetic permeability, of the substance in different parts of the surface. The dependence of the total quantity of electricity carried on extent of surface justifies Snow Harris, and proves that those who condemned him out of Ohm's law were wrong, in respect to his advising tubes or broad plates for lightning conductors, but does not justify him in bringing them down in the interior of a ship (even through the powder magazine) instead of across the deck and down its sides, or from the masts along the rigging and down the sides into the water.

Sir William Thomson read a paper on anti-effective copper in parallel conductors, or in coiled conductors for alternate currents. It is known that by making the conductors of a circuit too thick

we do not get the advantage of the whole conductivity of the metal for alternate currents. When the conductor is too thick, we have in part of it comparatively ineffective copper present; but, so far as is known, it has generally been supposed that the thicker the conductor the greater will be its whole effective conductance, and that thickening it too much can never do worse than add comparatively ineffective copper to that which is most effective in conveying the current. It might, however, be expected that we could get a positive augmentation of the effective ohmic resistance, because we know that the presence of copper in the neighbourhood of a circuit carrying alternating currents causes a virtual increase of the apparent ohmic resistance of the circuit in virtue of the heat generated by the currents induced in it. May it not be that anti-effective influence such as is thus produced by copper not forming part of the circuit can be produced by copper actually in the circuit, if too thick? Examining the question mathematically, Sir William finds that it must be answered in the affirmative, and that great augmentation of the effective ohmic resistance is actually produced if the conductor is too thick, especially in coils consisting of several layers of wire laid one over another in series around a cylindric or flat core, as in various forms of transformer.

Prof. J. A. Ewing, in a most interesting and important communication (*vide Phil. Mag.*, September 1890), exhibited a model to illustrate some novel ideas on the molecular theory of induced magnetism. The present notion of a quasi-frictional resistance opposing the turning of the molecular magnets lends itself well to account for the most obvious effects of magnetic hysteresis and the reduction of hysteresis by vibration. On the other hand, it conflicts with the fact that even the feeblest magnetic force induces some magnetism. Reference was made to another (and not at all arbitrary) condition of constraint, which not only suffices to explain all the phenomena of hysteresis, without any notion of friction, but seems to have in it abundant capability to account for every complexity of magnetic quality. Prof. Ewing supposes that each molecular magnet is perfectly free to turn except in so far as it is influenced by the mutual action of the entire system of molecular magnets. A model molecular structure was exhibited, consisting of a large number of short steel bar-magnets strongly magnetized, each pivoted upon a sharp vertical centre, and balanced to swing horizontally. The bars swing with but little friction, and their pole-strengths are sufficient to make the mutual forces quite mask the earth's directive force when they are set moderately near one another. The group is arranged on a board which slips into a large frame wound round the top, bottom, and two sides, with a coil, through which an adjustable current may be passed to expose the group to a nearly homogeneous external magnetic force.

Sir William Thomson read a paper on a method of determining in absolute measure the magnetic susceptibility of diamagnetic and feebly magnetic solids. The method proposed consisted in measuring the mechanical force experienced by a properly shaped portion of the substance investigated, placed with different parts of it in portions of magnetic field between which there was a large difference of the magnetic force. A cylindrical or rectangular or prismatic shape terminated by planes perpendicular to its length was the form chosen; the component magnetic force in the direction of its length was equal to $\frac{1}{2}\mu(R^2 - R'^2)A$; where μ denotes the magnetic susceptibility, R R' the magnetic force in the portions of the field occupied by its two ends, and A the area of its cross-section.

Lord Rayleigh read a paper on the tension of water surfaces, clear and contaminated, investigated by the method of ripples. The ripples were rendered visible by a combination of Foucault's optical arrangement with intermittent illumination. Two frequencies were used, about 43 and 128 per second. The surface-tension of a clean water surface, in c.g.s. measure, was found to be 74·0, thus confirming observations made with capillary tubes. Water saturated with olive oil had a surface-tension of 41·0, and saturated with oleate of soda a surface-tension of 25·0.

Mr. W. N. Shaw reported on the state of our knowledge of electrolysis and electro-chemistry.

Mr. J. Hopkinson read a paper on the inland compared with the maritime climate of England and Wales. For special reasons Buxton, Woburn (Apsley Guise), Croydon, Cheltenham, and Churchstoke were chosen to represent the interior of the country, while Scarborough, Lowestoft, Babbacombe, Worthing, and Llandudno were chosen to represent the sea-coast. The places were so chosen that the mean position, latitude, and longitude of the five inland places should closely approximate to those of the maritime. As the result of observations extending over the decade from 1880–89, he concluded that, so far as regards our comfort and most probably also our health, our maritime climate is on the whole superior to our inland climate, being warmer, owing (it is most important to observe) to the nights not being so cold, while the days are no hotter, the extremes of temperature being much less, the air rather less humid, the sky less cloudy, and the rainfall less.

Prof. Ramsay read a paper on the adiabatic curves for ether, gas and liquid, at high temperatures. The method adopted in the experiments was an ingenious one, and consisted in determining the velocity of sound in the vapour by Kundt's dust-figures, from observation of the wave-length and the pitch of the note emitted by the stroked tube containing the vapour. This process gives the ratio of adiabatic and isothermal elasticity from which the former elasticity can be calculated as the latter is known.

Prof. Ostwald read an interesting paper on the action of semi-permeable membranes in electrolysis, in which he gave an account of experiments upon the passage of an electric current through solutions in series separated by semi-permeable membranes, and pointed out the importance of such phenomena to physiology. He explained that a semi-permeable membrane would allow ions of one kind to pass through, but arrest ions of another kind, and thus act as though it were a metallic electrode.

Prof. C. Piazzi Smyth sent a paper on photographs of the invisible in solar spectroscopy. Two photographs were shown, each measuring 40 inches long × 20 inches high. They represent in reality, only very small portions of the faint ultra-violet of the solar spectrum, but on a whole scale of 57 feet long from red to violet; and are located quite outside the spectral limit of variability to the human eye, with the grating spectroscope concerned, whether under summer or winter sun.

Profs. Rücker and Thorpe contributed a paper on regional magnetic disturbances in the United Kingdom, and this was followed by a paper upon similar disturbances in France, by Prof. Mascart. A point of great interest in connection with these papers was the continuous nature of the disturbances extending from the one country across the Channel to the other.

Prof. Lodge, in a paper on electrostatic forces between conductors, gave an account of an investigation into the forces between electric resonators as examined experimentally by Boys, and therefrom branched out into several allied subjects connected with the mechanical forces of electric pulses and waves.

Prof. Fitzgerald communicated several papers on mathematical physics to the Section. One of these bore what would have been an attractive title, "An Episode in the Life of J," had it not been for a parenthetical addition, viz. "(Hertz's Solution of Maxwell's Equations)." It may be remarked that J has nothing to do with Joule or his equivalent, and that the episode referred to was not of the popular anecdotal type.

Mr. W. Barlow, in a paper on atom-grouping in crystals, called attention to some very interesting properties of the simpler kind of symmetrical grouping of points, and pointed out an easy and effectual method of studying them by using a model consisting of equidistant parallel planes of homogeneously distributed points represented by beads.

Mr. W. H. Preece read a paper on the character of steel used for permanent magnets. Samples of steel for the experiments were obtained from all the leading firms, and after magnetization were tested by a magnetometric method. The marked superiority of the Marchal magnets over those made of English steel is due either to the quality of the steel, or to the mode of tempering—most probably the latter.

Prof. S. P. Thompson read a paper on the use of fluor spar in optical instruments, in which he referred to the existing uses of fluor spar for experiments on radiant heat, and in the "apochromatic" microscope lenses of Zeiss. The latter application derives its importance from the extremely low dispersion relatively to the mean refractive power of the material. To these applications the author now added that of the construction of spectroscopic direct-vision prisms; and he described two prisms, both constructed for him by Mr. C. D. Ahrens—one consisting of a fluor prism cemented between two flint-glass prisms, and the second consisting of one Iceland-spar prism cemented between two fluor prisms. The former was considerably shorter than the ordinary direct-vision prism of equal power; the latter had the property of polarising the light as well as dispersing it, and presented the novel feature of a true polarispectroscope.

Mr. F. T. Trouton read a paper advocating the introduction of a coefficient of abrasion as an absolute measure of hardness.

Mr. F. H. Varley exhibited and explained the action of a new direct-reading photometer—an ingenious and compact instrument, in which intermittent illumination is employed for equalizing the intensity of illumination from two sources of light.

BIOLOGY AT THE BRITISH ASSOCIATION.

Although the number of papers in Section D was not quite so large as usual, it was found sufficient to occupy the time fully. As on previous occasions, the most attractive part of the proceedings was a discussion on a subject of general interest arranged beforehand, and opened by set papers.

After the President's address on Thursday, Prof. Newton gave an interesting account of the ornithology of the Sandwich Islands, discussing its peculiarities and probable affinities. He showed that the fauna is now undergoing modification, and is in danger of extermination on account of the changes which are rapidly being made in the vegetation of the islands; and he urged strongly the necessity of making a thorough examination of the fauna and flora of this important region while it is still possible. This paper led to the appointment of a committee, with a grant, for the purpose of seeing that the necessary exploration was carried out at once.

The usual reports on the zoology and botany of the West India Islands, on the migration of birds, on the disappearance of native plants, on a deep-sea tow-net, on the Botanical Station at Peradeniya, Ceylon, on the Biological Laboratory at Plymouth, and on the Zoological Station at Naples, were read, and the committees were reappointed.

The greater part of Friday's meeting was occupied by an important and interesting discussion on the teaching of botany, and especially the teaching in schools or to the young. The subject was opened with papers by Prof. Marshall Ward, Prof. F. W. Oliver, and Prof. F. O. Bower. Prof. Marshall Ward discussed the teaching of botany under the three heads: (1) elementary or school teaching; (2) more advanced or academic teaching; and (3) applied or special botany, such as forestry. He urged strongly the advantages of an early training in botany, and showed the suitability of the subject for school teaching, not however from books, but practically, and especially by means of field-work. In the teaching of applied botany he considered that principles and generalizations were of more importance than masses of facts, even in the training of the so-called practical man.

Prof. Oliver treated chiefly of the teaching of elementary botany to medical students at our colleges; and Prof. Bower dealt also with the arrangement of the usual junior University course, which he considered should be wide in its range and suggestive, rather than more restricted and exhaustive.

A number of other teachers of botany joined in the discussion; and Dr. Forsyth, of the Leeds Higher Grade School, showed that many of the suggestions which had been made were being carried out at his school, where the pupils were taken periodically to the fields to collect the specimens for their object lessons.

Prof. Marsh then gave an interesting account of the Cretaceous mammals of North America, of which he had now in his possession over 1000 specimens, all obtained during the last year or so. These remains all appear to belong to the lower forms of Mammalia, such as Monotremes and Marsupials, and are all of small size, although they are found in the same beds with the gigantic Dinosaurs, such as *Triceratops*.

Prof. Denny gave an account of an abnormality which he had found in three successive seasons in some flowers of *Tropæolum*, and which consisted in the inversion and in some cases duplication of the spur. Prof. Denny suggested that these abnormal flowers seemed to indicate that the spur was really the representative of the two missing stamens.

Canon Tristram contributed some notes on the natural history of Hierro and Graciosa, two outlying islands of the Canary Group. A paper by Mr. E. H. Hankin dealt with the modifying action of ferments, such as trypsin and pepsin, upon diseases caused by bacteria, *e.g.* anthrax. It is suggested that the injection of the ferment causes a "defensive proteid" to be formed and thrown into the circulation for the purpose of killing the bacteria.

On Monday, Prof. Miall and Mr. Hammond gave an account of the development of the head of the adult fly in the life-history of the dipterous insect *Chironomus*, commonly found in impure water. Prof. Marshall and Mr. Bles called attention to variability in development amongst allied animals, and even amongst individuals of the same species. Dr. P. H. Carpenter contributed notes on the anatomy and morphology of the Cystidea.

Mr. S. F. Harmer discussed the regeneration of lost parts in the Polyzoa, including the formation of new polypites in *Pedicellina* on the tips of the old stalks where no endodermal tissues are present. Dr. S. J. Hickson gave two papers on the Hydrocorallina—the one dealing with the meaning of the ampullæ in *Millepora murrayi*, which were found to contain modified dactylozooids bearing only very large sperm sacs; and the other being on the gonangia of *Distichopora* and *Allopora*. An important conclusion drawn from these investigations was that, as regards the position and character of the gonads, *Millepora* is not related to any of the Stylasteridæ.

Amongst a number of botanical papers read on Tuesday were: one by Mr. R. Warrington, showing that certain bacteria have the power, usually supposed to be peculiar to chlorophyll-bearing organisms, of forming organic compounds from inorganic materials; one by Prof. Bower, on the phylogenetic relationships between the different groups of Ferns; one by Prof. P. Geddes, on the origin of protandry and protogyny; and one by Dr. J. M. Macfarlane, on hybrids, in which it was shown from a number of genera of plants that certain hybrids which had been produced were intermediate, not only in appearance and general structure, but even in the most minute histological details, between the two parent species.

GEOGRAPHY AT THE BRITISH ASSOCIATION.

In the quality and scientific value of the papers, this Section was considerably above the average of last year. There were only about a score of papers altogether, but the Organizing Committee had determined rather to be short of papers than to accept any of trivial importance. As it was, the time of the Section during the four days on which it met was well filled up. The sittings were well attended, and sometimes almost crowded; which is saying much, considering the size of the hall in which the Section met. The Section adopted a plan which answered admirably. It adjourned each day from 1 to 2 p.m., and invariably a good audience assembled for the afternoon meeting.

The hall was well filled at the President's address, which was an excellent *résumé* of the physical geography of the Mediterranean and the regions around its shores. On two other occasions the lower part of the hall was quite filled by audiences evidently greatly interested. First, on the Monday, when there was a joint meeting of Sections E and F to discuss the important subject of the Lands of the Globe still available for European Settlement. Mr. E. G. Ravenstein opened the conference with a paper giving what may be called the geography of the subject. He excluded from consideration the Polar areas, desert areas, and tropical areas unsuited to a European population. He showed that, dealing with the subject from a purely theoretical point of view, the population of the world, at the present rate of increase, would, in about three or four generations, amount to something like 5000 millions. This, of course, sounds very alarming, but as in the case of the prediction of the exhaustion of our coal supply, it was shown during the discussion that we may keep our minds at ease. Prof. Marshall, Sir Rawson Rawson, Dr. Cunninghame, Mr. Bourne, and others who took part in the subsequent discussion, mainly from the economical point of view, suggested various considerations in modification of those derived from the purely theoretical standpoint. The earth has still vast undeveloped resources; a more equable distribution of these among mankind is possible, and even desirable; the theoretical rate of increase will certainly be modified in various ways; the so-called deserts may, actual experiment has shown, be made, by means of irrigation from underground supplies, both fertile and habitable. The great truth which came clearly out of the discussion—a truth which ought to be widely realized now that tropical Africa is being opened up—is that European colonization, in the proper sense of the term, is impossible, so far as present experience goes, between the tropics. There are, no doubt, modifying circumstances in some cases, but these are rare. As usual in such discussions, there was a certain amount of irrelevant talk;

but, on the whole, the conference quite fulfilled the expectations and the object of those who arranged it.

The hall was even more crowded, with an audience even more interested, on Tuesday morning, when Miss Menie Muriel Dowie read her paper on a journey in the Eastern Carpathians. It is the fashion in certain quarters to regard Europe as beyond the pale of geography; but to all but a very few of those who listened to Miss Dowie's delightful paper, what she had to tell about the Carpathians and their people was as new as Mr. Stanley's account of his great African forest.

Africa, of course, occupied a prominent place in the proceedings of the Section, one whole day being devoted to it. Dr. Kerr Cross, who has been stationed for many years in the Lake Nyassa region, and is well qualified for scientific observation, read a paper on the interesting plateau country lying between Lakes Nyassa, Hikwa or Leopold, and Tanganyika. The paper gave a most instructive picture of the extensive and varied area with which Dr. Cross is familiar. The information he gave about the little-known Lake Hikwa, east of the south end of Tanganyika, was specially valuable, as it had only been seen at a distance before by Mr. Joseph Thomson and a German explorer. It is brackish, of a long curved shape, and lies in a deep depression of the plateau, its basin being a parched-up wilderness. Though there has been abundant rain on the plateau around, for three years not a drop has fallen in the lake valley. Mr. E. A. Maund described in some detail Matabeleland, where he himself has resided for some years. Dr. R. A. Freeman's account of his journeys in Ashánti and neighbouring regions was of special novelty and value. The paper described a journey through a tract of country in and to the north of Upper Guinea, comprising the territories of Fánti, Assín, Ádánsi, Ashánti, Jáman, and Grúinsi. The tract extends from 5° N. to 10° N., and from 0° to 4° W. The first four countries are inhabited by various branches of the great Ōtshwí family, and the remainder by certain pagan aboriginal tribes, and by numbers of Wongára or Mandingo immigrants. Journeying from Cape Coast, through Ashánti to Bontúku, the capital of Jáman, the author crossed three zones of country: (1) open country covered with low bush about 30 miles broad; (2) dense forest about 180 miles broad; (3) open park-like country which, alternating with grassy plains, seems to occupy the greater part of Central and Eastern Africa. On arrival at Kumassi, the capital of Ashánti, the author was received by the king and principal chiefs with great ceremony, the court of Kumassi retaining much of its former splendour. The town of Kumassi is much dilapidated, but presents many relics of great interest. Jáman is a kingdom situated to the north-west of Ashánti, about 9300 square miles in extent; its capital, Bontúku, is a large town closely resembling in appearance the towns of the Tawarek and Upper Niger. It is inhabited almost exclusively by Mahommedans, and forms an important slave depot, as do also the Grúinsi towns of Wà and Bori. The commercial resources of the tract of country here described are considerable; over the whole of it gold is fairly plentiful, and the forest abounds in rubber plants both in the form of trees and vines. Hard woods are very plentiful, and are of great value in Europe, notably the Odúm and Pappáo, both of which trees reach a height of nearly 200 feet. The Kola nut also, which grows abundantly in the forest, has a great and increasing commercial value. The country is intersected by several considerable rivers which might be easily rendered navigable, and thus form great highways of trade. There are, moreover, no special obstacles to the construction of railways, and the district may thus be expected to form one of the great commercial centres of the future.

Mr. J. S. Keltie's paper on the Commercial Geography of Africa dealt with the varied physical conditions of the continent, and endeavoured to indicate the bearings of these on its industrial development and colonization. It was shown that the vast tropical region, in which Nature is most exuberant, is of insignificant commercial value compared with the countries along the Mediterranean and the region south of the Zambesi. Central Africa will only become of commercial value when, as in North and South Africa, man is able actively to interfere; the spontaneous animal and vegetable products of tropical countries can never be of great commercial importance.

Mr. A. Silva White followed with a paper showing in detail the partition of Africa among the Powers of Europe.

Two other papers of special African interest were read by Mr. Cope Whitehouse and Dr. Schlichter. The former sought to prove that in the oldest Ptolemaic maps a depression (Lacus Meridis) is shown, exactly corresponding to the Wadi Ráyan and Wadi Mullah. Dr. Schlichter, in an elaborate paper, discussed the whole subject of Ptolemy's knowledge of North-East Africa, and sought to show that many of his positions exactly corresponded with those of modern maps, obtained by quite recent explorations.

There were three papers connected with Asia. Mr. Theodore Bent's paper on his recent explorations in North-Eastern Cilicia was mainly of an archæological character. Sir Frederic Goldsmid read a paper on a railway through Southern Persia, as a link of communication in the great railway route that will one day connect England with India. Surveys and reports by recent travellers have rendered it easy to supply this link, which may be appropriately called the Baghdad-Bandar-Abbas section, or, more minutely, the Baghdad-Shiráz and Shiráz-Bandar-Abbas sections. As to the route from Bandar-Abbas to Karáchi on the east, and from Tripoli to Baghdad on the west, any doubts or difficulties that present themselves are already ripe for discussion, and their solution cannot be treated as dependent upon further travel and research. It is proposed to carry the line from Baghdad through Persian Arabistan, either by way of Dizful and Shustar, continuing along the recognized track from the latter place to Bebehan; or by an alternative route down the left bank of the Tigris, and *viâ* Haweizah to Ahwaz, whence Major Wells, R.E., has furnished full details of route from his own experiences. The same officer has made, moreover, very valuable suggestions on the mode of reaching Shiráz from Bebehan.

Mr. H. F. B. Lynch dealt with an allied subject in his paper on new trade routes into Persia. In the course of the paper Mr. Lynch, from his own personal knowledge, gave much information as to the physical geography of Persia, and especially the region watered by the Karun River.

South America was dealt with in two papers. Mr. J. W. Wells described the physical geography of Brazil in its bearing on the industrial development of the country, and M. A. Thouar sent an abstract narrative of his journeys during the past few years in the Argentine, Peru, and Bolivia.

Mr. Coutts Trotter gave a most useful summary of exploration in British New Guinea in recent years, dealing mainly with Sir W. Macgregor's journey to the summit of the Owen Stanley Range, already described in NATURE.

Dr. H. R. Mill gave a *résumé* of his investigations on the vertical relief of the globe, details of which have been published in the *Scottish Geographical Magazine*. He also gave an interesting account of his observations on the methods of teaching geography in Russia and of Russian geographical text-books.

Mr. Henry T. Crook's paper on the present state of the Ordnance Survey, and the paramount necessity for a thorough revision, led to the Sectional Committee's requesting the Council of the Association to move the Government to take steps for the rapid completion of the Survey, and for rendering the Ordnance maps much more accessible for purchase by the general public than they are at present.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

ON Thursday, September 4, after the President's address, a paper by the Rev. F. O. Morris, on the doctrine of hereditism was read, and gave rise to a lively discussion, or rather a chorus of condemnation of the views advanced by the author.

In a paper by Mr. Horatio Hale, which forms the introduction to the Report of the North-Western Tribes of Canada Committee, attention was called to some of the chief peculiarities of British Columbian ethnography, the great number of linguistic stocks which are found in this comparatively small territory and the singular manner in which they are distributed, especially the surprising variety of stocks clustered along the coast as contrasted with the wide sweep of the languages of the interior. All the languages of British Columbia have a peculiar phonology; their pronunciation is singularly harsh and indistinct; and it would appear that this is due mainly to climatic influences, for, south of the Columbia River, the harsh utterance suddenly ceases and gives place to softer sounds.

A paper by Mr. J. W. Fawcett was read on the religion of the Australian aborigines. The author stated that the Australians believe in a Creator, in a future life, and in good and

evil spirits. They have a strict sense of right and wrong, and have religious ceremonies, which are always held in secret on ground that is held very sacred, so much so that if it is touched by the foot of a white person it loses all sanctity.

Another paper by Mr. Fawcett was read on the aborigines of Australia, in which he traversed certain statements that have been made by Mr. Carl Lumholtz.

On Friday, September 5, Mr. F. W. Rudler, who, in the absence of Dr. Evans, presided over the Section, read a paper on the present aspect of the jade question.

It has long been known that implements worked in jade have occasionally been found in ancient graves in France and Western Germany, and in certain Neolithic stations on the Swiss lakes. Some of these implements are wrought in nephrite, or true jade, and others in jadeite. As neither of these minerals had been found *in situ* in Europe, while both were known to occur in Asia, it had been conjectured that the European jade implements must have had an Oriental source, and that either the implements themselves or the raw materials of which they were made had been brought to Europe in prehistoric times. But within the last few years Herr Traube, of Breslau, has discovered nephrite *in place* near Jordansmühl, and near Reichenstein, in Silesia. Pebbles of nephrite have also been recently recorded, by Dr. Berwerth, from the valleys of the Mur and the Sann, two rivers in Styria. A pebble believed to be of jadeite was found by M. Damour at Ouchy, on the Lake of Geneva, and the same mineral has been recorded from Monte Viso, in Piedmont.

Jade implements are found along the coast of British Columbia and Alaska, and it has been suggested that these, or the raw jade, had been obtained from Siberia, where the occurrence of nephrite is well known. Dr. G. M. Dawson has, however, recorded the discovery of small boulders of jade, partially worked, in the lower part of the Frazer River Valley; and Lieutenant Stoney has obtained the mineral *in situ* at the Jade Mountains in Alaska, 150 miles from above the mouth of the River Kowak.

The present aspect of the jade question is, therefore, quite different from that which it presented when the late Prof. H. Fischer and others strongly favoured the view that the jade implements of Europe and America had an exotic origin. In both these continents jade has now been found *in situ*, and it seems, therefore, probable that the material of the implements is indigenous, as maintained by Dr. A. B. Meyer for those of the Old World, and by Dr. Dawson, Prof. F. W. Clarke, Mr. G. F. Kunz, and others, for those of the New World. If future discoveries should confirm the indigenous view, the famous jade question will be lifted out of the domain of anthropology.

A paper entitled "Is there a Break in Mental Evolution?" was contributed by the Hon. Lady Welby. The introduction of the idea of "ghost" marks mental degeneration. If the idea of "spirit" had its origin in primitive man, it would have to undergo the most primitive tests, viz. *contact*, *odour*, and *flavour*. The author contended that we must either suppose an absolute break and reversal in the evolution of mind wherein a permanently distorted picture of the universe is created, and the real and significant suddenly abdicates in favour of the baseless and unmeaning; or, we must ask whether there is some reality answering to these crude conceptions, which thus form part of a continuous mental development, and may be described as faulty *translation*, rendered inevitable by the scantiness of primitive means of analysis and expression.

To adopt the first alternative is to strike a blow at the doctrine of continuous ascent in evolution: while the second might lead us to conclude that what we want is a greater power of interpreting primitive ideas as expressed in myth and ritual, notably in relation to recent developments and present researches in psychology itself and the psychological aspects of language.

Dr. Phené read a paper on an unidentified people occupying parts of Britain in pre-Roman-British times. From extensive investigations in France, Italy, &c., he showed that certain names and words continued from Britain to the Mediterranean along ancient routes of traffic, and the works and constructions along, and in connection with, the same routes, were so alike as to be identical in design. These constructors and merchants were not British, and the traffic appears carried back long prior to the time of Cæsar.

The other papers read were on the Yourouks of Asia Minor, by Mr. T. Bent; the Aryan cradle-land, by Mr. J. Stuart Glennie; and reversions, by Miss Nina Layard. The Report of the Notes and Queries Committee was also presented.

On Monday, September 8, Dr. G. W. Hambleton read a paper on physical development, in which he described the results of a practical experiment in physical development which is being carried on at the Polytechnic Institution. Fifty per cent. of the 200 members of the author's Physical Development Society had obtained an increase of chest-girth of one inch and upwards, the average increase being a little less than two inches. In one case the increase was 6½ inches. The increase has taken place in small as well as in large chests, whether the men were tall or short, under or over twenty-one years of age, and with or without gymnastic training.

Dr. Munro described some archæological remains bearing on the question of the origin of the Anglo-Saxons in England. The relics in question have been recently brought to light on the coasts of Holland and North Germany, more especially in Friesland and the low-lying district northwards as far as the River Elbe, and show a remarkable similarity to Anglo-Saxon antiquities found in England. Dr. Munro also contributed a paper on prehistoric otter and beaver traps, in which he described some curious wooden machines which have been discovered in various peat bogs in different parts of Europe, and of which hitherto no satisfactory explanation has been offered.

Rev. E. Maule Cole read a paper on the Duggleby "Howe." This great mound on the Yorkshire wolds was opened by Mr. J. R. Mortimer on behalf of Sir Tatton Sykes in July last. The diameter of the mound was found to be over 120 feet, and the height was originally about 30 feet. In the process of excavation it turned out that there was an outer mound of rough chalk, of some 15 feet or more in thickness, surrounding an inner mound, and that the centres of the two did not exactly correspond. In the grit and lower clay were found fifty-three deposits of burnt human bones, but without any urns. Some beautiful flint weapons and tusks of the wild boar were discovered with human bodies in graves cut out of the solid rock.

Mr. J. R. Mortimer described a Romano-British graveyard in the parish of Wetwang-with-Fimber, which he believes to be the site of the long-lost Delgovitia.

Mr. Mortimer also contributed a paper on a supposed Roman camp at Octon, close to the road from York to the coast. The rectangular corners of the camp, and the width of the ditches (7½ feet) at the bottom, encourage the belief that this is not a British work, but Roman.

The other papers were on minute Neolithic implements, by Dr. H. C. March; indications of retrogression in prehistoric civilization in the Thames Valley, by Mr. H. Stopes; and a suggestion as to the boring of stone-hammers, by Mr. W. Horne.

On Tuesday, September 9, Dr. Wilberforce Smith read a paper on stethographic tracings of male and female respiratory movements. The investigation of the author, so far as it has yet proceeded, totally fails to confirm the view commonly put forth in physiological text-books that there is a natural difference between the sexes in regard to respiratory movements. Mr. W. F. Stanley exhibited and described a new spirometer, constructed upon the principle of the class of gas-meters used for testing. Dr. J. G. Garson contributed some notes on human remains found by General Pitt-Rivers, at Woodyates, Wiltshire. The measurements of the limb bones showed the stature of the persons to have been greater than that of those who were interred in Woodcuts and Rotherley. The characters of the skulls showed a considerable range of variation in size and proportion, indicating that they did not belong to a homogeneous people, but to individuals of mixed race. Variation was found not only in the facial portion, but also in the form of the calvaria. As far as the author was able to judge, the mixture is due to crossing between the Romans and the early dolichocephalic British race. There is no evidence of mixture arising from crossing between either of these races and the Celtic population.

The following papers were also read: Mr. B. Hollander, old and modern phrenology; Dr. Wilberforce Smith, diagrams for reading off indices; General Pitt-Rivers, excavation of the Wandsdyke at Woodyates; together with the report of the Anthropometric Laboratory Committee; report of the Prehistoric Inhabitants Committee; report of the Nomad Tribes of Asia Minor Committee; report of the North-Western Tribes of Canada Committee; and the report of the Indian Committee.

THE VOLCANOES OF THE TABLE LAND OF MEXICO.

THE following account with extracts is based on information gathered from a notice which appeared in the *Philadelphia Public Ledger*, sent us by the courtesy of Prof. Heilprin. He had been obliged to issue the notice in advance of the full publication of his papers by the Academy of Natural Sciences of Philadelphia, as he found on his return many varying reports of the work carried on in Mexico.

Amongst the most recent determinations of the heights of these great volcanoes are those made by the Mexican Expedition lately organized under the auspices of the Academy of Natural Sciences of Philadelphia. Prof. Heilprin has recently placed on record his barometric determinations of the four loftiest summits of the Mexican Republic: Orizaba, Popocatepetl, Ixtaccihuatl, and the Nevado de Toluca. In this paper he points out that the highest point of the Republic is the Citlaltepetl or Star Mountain, more commonly called the Peak of Orizaba, and not Popocatepetl as is generally assumed by the Mexican geographers. All his observations were made "with a carefully tested aneroid barometer, and the data were computed from almost simultaneous observations at the Mexican Central Observatory of the City of Mexico, and from barometric readings made at the sea-level at Vera Cruz. The equable condition of the atmosphere, at the time these observations were made, rendered the possibility of the occurrence of possible errors of magnitude almost *nil*." From the above quotation it will be seen that great care was taken to eliminate all errors and to get as accurate measurements as possible.

Popocatepetl was commonly accepted as the highest peak, and Alexander von Humboldt recorded it in 1804 as 17,720 feet. Since the above date, many trigonometrical surveys have been made, and the results vary from 17,200 feet to a few feet over 18,000. The latest measurements by Prof. Heilprin give 17,523 feet as the height, being 200 feet lower than Humboldt's estimate. This determination has been derived from the newer data which have been made possible through the levelling of the Mexican Railway, which was constructed a few years since, while geographers have almost universally accepted Humboldt's determinations and figures. From these new data it was shown that "the estimate of the elevation of the city of Mexico (7470 feet), and of the adjoining plateaus, which have served as a basis for most of the angle measurements of the mountains, have been placed 123 feet high. Allowing for this excess, a striking correspondence is established between the early measurements and those obtained in the spring of the year by the Philadelphia Expedition."

Prof. Heilprin and Mr. F. C. Baker made the ascent of this mountain on April 16 and 17, reaching the "rim of the crater at 11.30 o'clock on the morning of the 17th, and the culminating point early in the afternoon of the same day. Little difficulty was encountered in the ascent beyond that which is due to inconvenience arising from the highly rarefied atmosphere. The snow-field was found to be of limited extent, and not more than from five to ten feet in depth, and was virtually absent from the apex of the mountain. The surprisingly mild temperature of the summit, 45° Fahrenheit, rendered a stay of several hours in cloudland very delightful."

The supposed second highest summit of the Mexican Republic is the mountain of Orizaba or Citlaltepetl, and "the results of Prof. Heilprin's determinations show more marked variations from those of most of the earlier investigators, and more particularly from those of Humboldt." The height determined by Humboldt by means of angles taken from near the town of Galapa, was 17,375 feet, while Ferrer's determination in 1796 gave 17,879 feet, as recorded in the Transactions of the American Philosophical Society. The latter value is generally adopted by the German geographers, while the Mexican geographers, on the other hand, adopted the measurement of Humboldt, or "that which was obtained by the National Commissions of 1877, indicating a height of 17,664 feet."

The following is a short account of the ascent:—"Prof. Heilprin, with three of his scientific associates and eleven guides, made the ascent on April 6 and 7, or ten days before the ascent of Popocatepetl. The last camp, at a height of some 13,000 feet, was left shortly before five o'clock in the morning of the second day, and after a difficult and continuous struggle of twelve hours through loose boulders, sand, and a much cut up ice cap, the party—or rather the fragment which succeeded in holding out—finally reached the rim of the crater." At this point, about 120 feet below the apex of the cone, Prof. Heilprin made a measurement which indicated a total height of 18,206 feet, exceeding Ferrers and Humboldt's measures by 325 and 860 feet respectively.

As upon Popocatepetl, "the snow cap, upon Orizaba, although arising 2400 feet, or nearly half a mile above the summit of the highest peak of the Alps, was a comparatively insignificant development." The time spent on the summit was short, lasting only a quarter of an hour, and then followed the descent through the numerous seracs of the ice, which proved most difficult. At a little past eight o'clock in the evening the camp was reached, thus completing "a remarkable round of mountain climbing of fifteen successive hours."

Prof. Heilprin describes the views from the slopes of the mountain as surpassingly grand, exceeding anything that he had seen in his travels. "Far off to the west the giants Popocatepetl and Ixtaccihuatl were clearly outlined against the sky at a distance of about 100 miles, while to the east and south the eye wandered over a seemingly endless expanse of plateaus and lowlands, penetrating through a series of successive cloud planes." The measurements of both the peaks of Orizaba and Popocatepetl were made under very similar conditions of the atmosphere; the same instruments were used, and there was only an interval of ten days between the measurements, which points to the conclusion that "the first place among Mexican volcanoes must be accorded to the Star Mountain."

On the 27th of the same month the ascent of the third highest peak, called the Ixtaccihuatl, was made. The general appearance of this mountain differs considerably from the two mentioned above; instead of having a symmetrical or conical outline, it has "a strong flowing crest, covered with a heavy deposit, some 75 or 100 feet in thickness, of snow and ice, which serves readily to distinguish the familiar 'White Woman' of the plain of Anahuac."

The measurement obtained by Prof. Heilprin of the height of this mountain is 16,962 feet, which height differs by 800 to 1300 feet respectively, from those formerly obtained by the Mexican geographers. Sonntag, in the year 1857, also determined its height, and his result accords very closely (within 11 feet) with Prof. Heilprin's. The temperature on the summit was found to be lower than that on either of the other two peaks, the thermometer indicating 32° F.

In view of the close proximity of this mountain to Popocatepetl, it is difficult "to account for the low value given by Humboldt and the Mexican geographers. So nearly do they appear of equal height that the eye at first fails to distinguish which of the two summits is the higher. German geographers, however, in a few cases, have adopted Sonntag's measurements, neglecting, as in the case of Popocatepetl, to make allowances for the error in this case of 125 feet which is indicated by the levelling of the Mexican Railway."

On April 2, Prof. Heilprin and Mr. Baker ascended the fourth highest summit of the Republic, the Nevado de Toluca. The ascent of this mountain is much easier than the others, and the summit can be reached on horseback to within a distance of 900 feet. The rim of the broken crater "is extremely ragged and narrow, descending with equal abruptness to the inner and outer faces of the volcano. At some points the crest is so attenuated that it can be readily straddled." The height of this mountain was found to be 14,952 feet, which approximately corresponds to the mean between Humboldt's determination and those made by a class of students from the School of Engineers of the city of Toluca.

The results of the measurements of this mountain are very divergent, as will be seen by the following list. La Pérouse, in 1786, gave the height as less than 13,000 feet. The British Hydrographic Chart of 1872 gave 14,970 feet, and this estimate is the one which is generally followed by the English and a number of American geographers. Malespina, in 1791, by means of angles taken from positions near Fort Mulgrave, determined the height to be 17,851 feet, while Tebenkoff reduces this figure by about 900 feet.

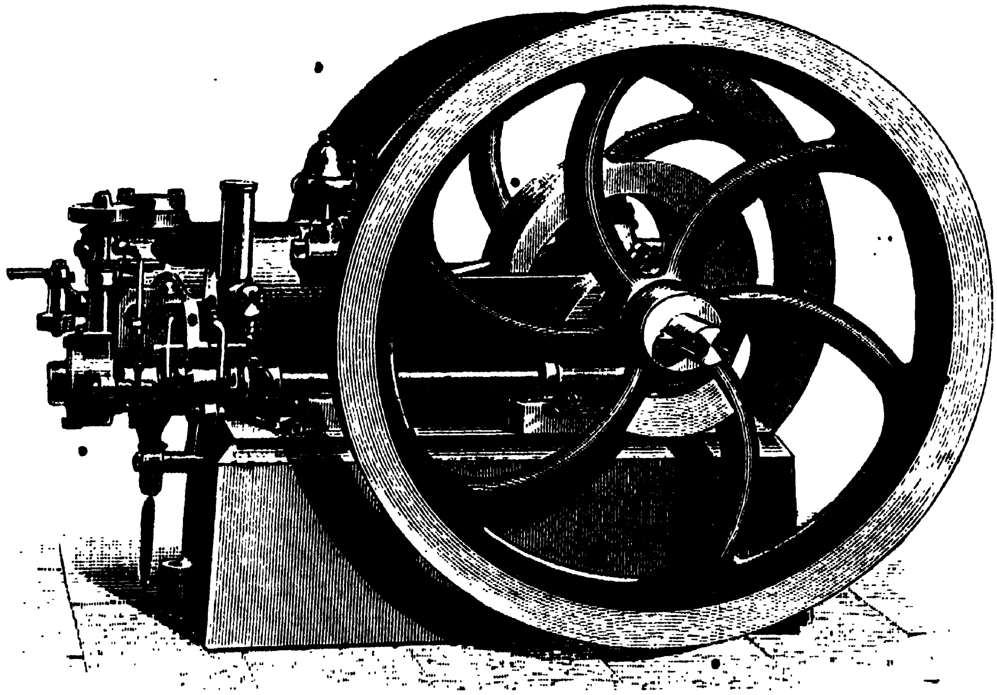
The most carefully conducted series of measurements are "those which were made by Mr. W. H. Dall, under the auspices of the United States Coast Survey, 1874. These yielded results ranging from a little more than 18,000 to nearly 20,000 feet. The measurements were made from distances 69, 127, and 167 miles, and it is more likely that the discrepancy in the results obtained is due to an uncertainty regarding the actual position of

the mountain." Even in these latter measurements we have results in which the extreme variation is about 2000 feet, and this distance compared with 4 miles (about the height of the mountain) is a large quantity, and shows that a still more accurate determination must be made before its height is placed beyond doubt.

From the results of the measurements of the heights of these four mountains, the existing evidence seems to point to the "Star Mountain" of Mexico, the peak of Orizaba, with its 18,200 feet, as the culminating point of the North American continent.

A NEW ELECTRIC LIGHT OTTO GAS-ENGINE.

ELECTRIC lighting is becoming so universal in all parts at the present day, that we give an illustration of the latest form of gas-engine made by Crossley and Brothers, Manchester. This engine, called the "High Speed Electric Light Otto Gas-Engine," runs at 250 revolutions, and is designed throughout to run at this exceptional speed. It is fitted with most of the latest improvements, such as Crossley's tube ignition, patent timing valve, and a special electric light governor, which makes it a very steady running engine for this kind of



work. The makers claim that "electric light lamps can be driven direct from the dynamo without fitting the dynamo with a fly-wheel or disc, as has hitherto been done when a small gas or steam-engine has been used; and that the light will be as absolutely steady as is possible with any form of motive power."

SCIENTIFIC SERIALS.

THE *American Meteorological Journal* for September contains an article, by Prof. H. A. Hazen, on Espy's experiments on storm generation and the liberation of latent heat on cloud-formation; these were made about 50 years ago, and Prof. Hazen states that they have never been checked, but have been accepted without question by meteorologists. His own experiments have led to different results, and he finds that deposition from *moist* air does not set free latent heat.—E. B. Garriott contributes an article on the origin of storms; he attributes their development to an excess of heat from the earth's surface by radiation, and their progressive movement to the precipitation of aqueous vapour at a considerable elevation, while the direction in which they move is regulated by the disposition of cold dry air found in areas of high pressure. For a verification of these facts, he points to the storms of the North American continent, a large majority of which originate over the great plateau region in the lee of the Pacific coast ranges of mountains, and advance towards the regions of greatest moisture which embrace the Great Lakes, the Gulf of Mexico, and the valleys of the principal rivers.—M. Faye has a supplementary article on trombes and tornadoes, for the purpose of introducing the figures illustrating his previous papers in the *Journal*.—Mr. M. W. Harrington contributes an instructive paper on forests and soil temperatures. He has taken various sets of observations published in Germany and elsewhere, amounting altogether to 150 years, and has discussed them by harmonic analysis for various periods, with the view of finding the distribution of temperatures in the soil within and out of the forest, at any depth, and at any time. The greatest difference between the forest soil and that of the open fields is at the surface, the mean difference of forest below open field being about 3°, but below the surface the differences between forest and open field do not progress uniformly. There appears to be a gain of heat in the upper soil of the woods which the open fields do not have.

American Journal of Mathematics, vol. xiii., No. 1 (Baltimore, October 1890).—The opening paper (pp. 1–52), entitled "Ueber die zu der Curve $\lambda^3\mu + \mu^3\nu + \nu^3\lambda = 0$ im projectiven Sinne gehörende mehrfache Ueberdeckung der Ebene," is by Mellen Woodman Haskell, a name not familiar to us, but belonging evidently to a mathematician of power. The discussion is exhaustive, and is fully illustrated with diagrams in the text, and two large-paged tables containing shaded diagrams. The reader who is familiar with Klein's "Ueber eine neue Art Riemann'scher Flächen" will easily follow the author's work. An index supplies the student with a ready key to the matters handled.—Prof. Cayley (pp. 53–58), in a note on a soluble quintic equation, discusses one of the equations given in Mr. Young's paper, "Soluble Quintic Equations with Commensurable Coefficients" (vol. x. pp. 99–130). The example considered is $x^5 + 3x^2 + 2x - 1 = 0$, the solutions of which the author shows admit of being put in much simpler form than those given by Mr. Young.—Then there is an instalment of a course of lectures delivered at the Johns Hopkins University during the months of January and February 1889, by Oskar Bolza. Its title is "On the Theory of Substitution-groups, and its Applications to Algebraic Equations." The paper is divided into two parts. The *first* develops the fundamental propositions, and concludes with a

short sketch of the extension of the theory to groups of operations in general. The *second part* deals with Galois's theory of algebraic equations, in particular their solution by radicals. The material is taken from Jordan, "Traité des Substitutions"; Serret, "Cours d'Algèbre Supérieure"; and Netto, "Substitutionen-Theorie." Other authors have been consulted, and the whole has been strongly influenced by a course of lectures on the subject by Prof. Klein. The editor of the *Journal* expresses a belief that this development will prove extremely useful to students.—This being the opening number of a new volume, is graced by a fine portrait of Prof. Cayley, which gives a very truthful presentment of this eminent mathematician's characteristic features.

IN the numbers of the *Journal of Botany* for August and September is an interesting mycological contribution from Dr. A. Barclay, describing some of the Ustilagineæ and Uredineæ parasitic on cereal crops and other crops in India. The most important of these are the following: *Puccinia Sorghi* on *Sorghum vulgare*, *Melampsora Lini* on *Linum usitatissimum*, *Uromyces Pisi* on *Cicer arietinum* and on *Lathyrus sativus*, *Puccinia Fagopyri* on *Fagopyrum esculentum*. Mr. W. H. Beeby contributes a paper on the British species of *Sparganium*; as regards fertilization, he states that they are rarely visited by insects; they are all proterogynous, and mostly wind-fertilized. Among the "Short Notes" is the very interesting record of the occurrence of the very rare *Ranunculus ophioglossifolius* in Gloucestershire.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 29.—M. Duchartre in the chair.—On the theory of infectious disease, of recovery, of vaccination, and of natural immunity, by M. Ch. Bouchard.—On the absorption of carbon monoxide by rocks, by M. Berthelot. Observations in mines after explosions have been said to indicate that the rocks of which the walls are constituted possess a specific property by virtue of which they retain carbon monoxide in their pores for a longer period than other gases. From some experiments made to investigate this question, M. Berthelot finds that the volume of carbon monoxide absorbed by argillaceous rocks and given up by them, is sensibly identical with the volume of air absorbed and given up under the same conditions. Hence, rocks impregnated with carbon monoxide owing to an explosion do not retain it because of any specific action peculiar to this gas.—On acetylene condensed by the silent discharge, by the same author. An examination of the result of the condensation of acetylene by means of the silent discharge appears to indicate that it differs in character from that obtained by the influence of heat on the same compound.—Spark spectrum of gadolinium, by M. Lecoq de Boisbaudran. The author gives the wave-lengths of the lines, bands, and flutings characteristic of the spectrum of gadolinium.—On the atomic weight of terbium metals, by the same author. The value found from two experiments was 159·48.—On a new safety-lamp for use in mines, by M. Charles Pollak. The lamp is an incandescent one. It weighs about 1800 grammes, and will give a light equal to 0·7 or 0·8 of a candle-power for twelve hours. Observations of Comets Coggia and Denning (*b* and *c* 1890), made with the great equatorial of Bordeaux Observatory, by MM. G. Rayet, L. Picart, and Courty. Observations for position were made on July 27 and 29 and on August 6 in the case of the former comet, and on September 14 and 15 in the case of the latter.—Thermo-electric researches, by MM. Chassagny and H. Abraham. The authors find, from some experiments, that the variation in the electromotive force produced by heating the poles of a copper-iron couple is practically constant between 0° and 100° C. It is therefore possible that thermo-electric elements may serve as standards of electromotive force better than electro-chemical cells. The same results were found with couples two months old as with those only two days old.—On a fungus of the Mucedinean group, by M. Raphael Blanchard.—On the properties of the principal natural colouring-matters of yellow silk, and their similarity to those of carrotin, by M. Raphael Dubois. Evidence is adduced to show that raw yellow silk owes its colour to the presence of a substance analogous to the colouring-matter recently extracted from the *Diaptomus denticornis*, by M. Blanchard, and considered as a carrotin of animal origin.—The identity in the structure of lightning and discharges from an induction machine, by M. E. L. Trouvelot.

STOCKHOLM.

Royal Academy of Sciences, September 17.—On the discovery of cerium minerals and columbite, and on the occurrence of microlite, by Baron Nordenskiöld.—On the discovery of pinakiolite, trimerite, and centrolite, by G. Flink, communicated by Prof. Brögger.—On inclosures of dissimilar rocks in some Scandinavian diabases, by Herr H. Bäckström.—On maxima and minima by double integrals, by Dr. O. Kobb.—On a generalization of the Bernoullian functions, and their connection with the generalized series of Riemann, by Dr. A. Jonquière, of Basel.—Some formulæ of Bierens de Haan, by Dr. Lindman.—Études de la distribution spectrale de l'absorption dans le spectre infra-rouge, by Dr. K. Ångström.—On phenyl-totyl and benzylen-diamin, by Dr. Söderbaum and Prof. Widman.—Derivatives of ortho-amido-benzyl-alcohol, iii., by Dr. Söderbaum.—Researches on the conductibility of the caloric in porous humid bodies, by Herr S. A. Andrée, C.E.—On the new edition of the collected works of Galileo, by Dr. G. Eneström.

AMSTERDAM.

Royal Academy of Sciences, September 27.—Prof. van de Sande Bakhuysen in the chair.—Prof. Schoute dealt with some general theorems relating to directly similar plane figures.—Prof. Hubrecht described phases in the early development of the shrew's placenta, and called attention to the fact that, whereas in the hedgehog the uterine epithelium disappears—the subepithelial stroma forming the maternal contribution to the placenta—in the shrew, on the contrary, this contribution is directly derived from the epithelium of the uterus.

ANALYTICAL MECHANICS.

A Treatise on Analytical Mechanics. By Bartholomew Price, M.A., F.R.S., F.R.A.S., Sedleian Professor of Natural Philosophy, Oxford. Vol. II. Dynamics of a Material System. Second Edition. (Oxford: Clarendon Press, 1889.)

A SECOND title-page describes the present work as volume iv. of "A Treatise on Infinitesimal Calculus," so that Prof. Bartholomew Price's well-known four volumes may be taken to represent the curriculum of the Infinitesimal Calculus and its applications for the mathematical student at Oxford.

To one accustomed to the style of the text-books in use at Cambridge, the contrast is very striking; the Oxford student is much to be envied for the leisurely and luxuriant way in which the subject is here presented, which follows on the lines of Lagrange and Laplace, and utilizes all the resources of analysis. A student who has been through the present work will be prepared to appreciate the purely geometrical form in which the Newtonian methods, insisted upon at Cambridge, would present some of the theorems in a more fundamental and incisive form; but to our mind the Cambridge system is inferior, which ostensibly insists on the purely geometrical methods before allowing the student to make use of the power of analysis.

Although Newton claims to be one of the inventors of this Calculus, and must have employed its methods in the discovery of his theorems, yet he carefully covered up all traces of the analytical scaffolding, and exhibited a theorem in the "Principia," like a Greek temple, in pure geometrical form.

His influence on his successors was too great when they attempted to follow in the same lines, with the consequence that our insular school of mathematics lagged hopelessly in rear of Continental progress.

Although prescribed as the text-book at Cambridge, the "Principia" is not studied in the original Latin, as Newton wrote it, from one end to the other; but the student makes use of commentaries and selections, which, in accordance with the regulations, he professes to appreciate and apply, before knowing even by sight the supposed mystifying symbols of dy/dx and $\int ydx$.

We might as well send out our soldiers armed with muzzling loading guns, or even bows and arrows, to meet a continental army equipped with the most recent inventions of magazine rifles and breech-loading artillery.

Thus the late R. A. Proctor could write that, although a wrangler, he knew nothing of the Differential Calculus till some time afterwards, when he had to pick it up of himself; however, by a recent regulation, only passed a few weeks ago, a most stupendous change has been made in the Mathematical Tripos, by prescribing a certain very elementary course of Analytical Geometry and the Calculus in the First Three Days.

At Cambridge the large number of candidates for mathematical honours acts as a check to change; and as the same papers have to serve for such widely different classes as the wranglers and the junior optimes, it may happen that a candidate who merely writes out book-work will beat a better mathematician who is tempted to try the difficult questions.

The number of students in mathematics at Oxford is much smaller, and the standard for honours is higher; so that we can take this treatise on Infinitesimal Calculus and contrast it with the extracts from Newton's "Principia," to illustrate the relative standards.

Under the enthusiastic influence of a Sylvester we may see the mathematical school at Oxford the first in this country, as it was two hundred years ago, in the days of Wren, Wallis, Keill, and the founders of the Royal Society, which had its origin in Oxford.

At the outset of the Dynamics of a Material System in space, it is necessary to discuss a number of theorems in solid geometry on the distribution of principal axes and the associated theorems of confocal quadrics (chapter i.); also the kinematics of a rigid body, involving the composition and revolution of angular velocities, and the transformation of co-ordinate axes (chapter ii.).

The author could simplify the distinction between the two systems of rectangular axes by adopting Maxwell's comparison with the screw, right-handed or left-handed. All specifications of rotation as clock-wise, or counter-clock-wise, are ambiguous; because the direction changes as we pass from one side to the other of the clock face. Standing at dusk about a quarter of a mile from a windmill, nearly in the plane of the sails, it is possible by a slight mental effort to change the apparent direction of rotation, and back again, as often as we please.

The author does not permit himself the use of the elliptic functions; or else he would have found the wonderful chapter i., t. ii., of Halphen's "Fonctions Elliptiques" of great service in giving the representation of the cosines of the angles which a movable straight line or a movable set of three rectangular axes makes with three fixed rectangular axes. Much of the subsequent work on Euler's three angles, the integration of his equations of motion, and of the spherical pendulum, &c., could be completed and the integrations effected by the use of Halphen's formulas.

Dynamics proper is introduced in chapter iii., where D'Alembert's principle is employed to establish the equations of motion of a material system, with the subsequent corollaries of the independence of the motions of translation and rotation, and the principles of the conservation of momentum and energy.

It is more the fashion now to dispense with D'Alembert's principle, and to refer immediately to Newton's third law of motion; still, D'Alembert's principle, although a mere corollary, states the thing in such a way as to lead immediately to the formation of the six equations of motion; and by stating it in such a manner as to reduce all dynamical principles to a statical form—"the reversed effective forces and the impressed forces form a system in equilibrium, the internal cohesive forces (stresses) being in equilibrium among themselves."—it was formerly considered that a simplification was effected.

But Maxwell, in his "Matter and Motion," by considering Newton's third law of motion as merely the definition of a *stress*, has been able to restate all the theorems involved in D'Alembert's principle in a few simple sentences, and in a much more convincing form.

It is a pity that the term *vis viva* has been allowed to remain in this last edition, and that it was not entirely replaced by *kinetic energy*: the contrasted term *vis mortua* has been dead for a long time, and *vis viva* should have followed long ago.

The transformations of the dynamical equations into the Lagrangian and Hamiltonian forms are introduced at rather an early stage; and the subject is resumed in the last chapter x., on "Theoretical Dynamics," written by the late Prof. W. F. Donkin. These transformations are merely analytical illustrations of the change of independent variables, the form of the equations depending on whether we express the kinetic energy in terms of the generalized velocities or the generalized momenta.

A clear and expressive notation, somewhat in the style of that found necessary in Thermodynamics, would make these equations more intelligible and convincing; but in any case, the application to definite problems, especially where the geometrical constraints present any peculiarity, is so difficult and refined, that these equations are dangerous weapons to put into the hands of any but advanced students.

The principles of Least Action and of Least Constraint are also introduced here by the author; interesting verifications are thus afforded of well-known problems; but these principles again would not be employed for choice; and although the author pleads in their favour, we think it should not be forgotten that the principle of Least Action was employed to bolster up the Corpuscular Theory of Light.

Newton's principle of mechanical similitude, in the next section, is, however, of great practical importance, and we see its application in the constantly increasing size of our bridges, ships, and guns. In its particular application to naval architecture, a corollary goes by the name of Froude's law (also enunciated by Reech), which asserts that in similar vessels run at speeds proportional to the square root of the length or the sixth root of the displacements, the resistances are as the displacements; and thus the naval architect is able to infer, from the known performance of a ship or a model, what to expect on a different scale. When we make, in any two similar machines of the same material, the velocities in the ratio of the square root of the linear dimensions, we ensure in this manner that the stress per unit area in the material is the same, and thus the two machines are equally strong; so that this law of corresponding speed is most useful in the practical application of Newton's law of similitude.

A valuable section on Units, No. 9, points out that there are only two systems which need be considered: the British foot-pound-second (F.P.S.) system, and the metric centimetre-gramme-second (C.G.S.) system. The author's numbers for the conversion of one system into the other are not exactly according to the latest determinations; thus it is more accurate to make 1 metre = 39·37079 inches, and 1 foot = 30·4794 centimetres. The metre was originally designed so that the kilometre should be the centesimal minute of latitude, for use in navigation; but taking the sexagesimal minute of latitude as 6080 feet, the Admiralty standard, then the above figures make the length of the earth's quadrant 10,007 kilometres, instead of 10,000, as designed. It has been decided, however, for electrical purposes that 10^9 centimetres should be called a *quadrant*, although about 0·07 per cent. out.

Recent redeterminations of the weight of a metre cube of water, and of the volume of 10 gallons or 100 pounds of water, made with the greatest care, have revealed perceptible discrepancies with former estimates; so that the definition of the kilogramme as a decimetre cube of pure water at its maximum density must be considered a purely academic definition, and not sufficiently precise for legal purposes; the ultimate appeal being to the lump of platinum preserved in the Conservatoire des Arts et Métiers.

A Committee of the British Association is at present engaged in attempting to fill up the gaps in our dynamical terminology: the author introduces the *dyne* and *erg*, due to a former Committee, but not the *kine*, *spoud*, *bole*, and *barad*, recently settled upon as names for the C.G.S. units of velocity, acceleration, momentum, and pressure. The C.G.S. units are too minute for practical purposes, so that electricians now employ the *joule*, of 10^7 ergs, and the *watt* as the volt-ampere, or power doing one joule per second—units based really upon the commercial units of the metre and kilogramme, instead of the centimetre and the gramme. These microscopic units were adopted by the original Committee apparently merely to gratify the fad of making $W = sV$, instead of $1000sV$.

The astronomical unit of mass is defined in § 143; but if it is difficult to measure the volume of a kilogramme of water, the probable error in the determination of this astronomical unit of mass is immensely greater; so that to our mind this unit had better be discarded, and the gravitation constant introduced into the equations, using its provisional value, $10^{-8} \times 6{\cdot}48$ C.G.S. units (Everett, Units and Physical Constants," § 72).

Chapter iv. discusses the equations of motion of a rigid body expressed in terms of angular velocities and their increments, &c. The author adopts various illustrative methods, but to our mind the simplest procedure is to establish the general equations, with the usual notation $\dot{h}_1 - h_2\theta_3 + h_3\theta_2 = L, \ldots$; and then Euler's equations, &c., follow as particular cases. By adding the terms due to the employment of a movable origin we obtain the form of the Hamiltonian equations required in the discussion of the motion of a body moving in a liquid; and here is a good opportunity for the introduction of Dr. Routh's principle of the Ignoration of Co-ordinates, required to complete the theory of the generalized equations of motion.

Prof. Price could make a very useful book for students of elementary mathematics by taking out and printing separately the part on uniplanar motion and its illustrative examples (chapter v.): the complication of the subject of rigid dynamics is more than doubled when we consider motion in three dimensions; but in two dimensions the subject is within the grasp of most students, who will thus acquire a good working knowledge sufficient for most purposes. At the outset the determination of simple moments of inertia is required, and this involves a knowledge of integration; so that a student, untrained in the Calculus, can make very little headway. It is a pity that the lack of the slight knowledge of integration required for this purpose prevents most of our students from going on to the real study of the pendulum, the motion of the

wheel and wheeled carriage, and of the ballistic pendulum Prof. Price calls the inventor Captain Robins; but according to the preface of his "Mathematical Tracts," Robins was of Quaker extraction (like so many other students and inventors of warlike instruments), and his only military employment was as chief engineer of the East India Company, in planning and carrying out their fortifications.

In chapter vi. the rotation of a rigid body about a fixed point is discussed, with applications to the three important problems of motion under no forces with Poinsot's geometrical representation, the motion of the top or gyrostat, and the precession and nutation of the earth's axis. These problems illustrate very strikingly the great increase in complication when we go from plane motion to motion in space. The figure of the herpolhode, on p. 251, shows points of inflexion; but, as the author mentions in § 295, these points of inflexion cannot exist in Poinsot's herpolhode. An elegant geometrical demonstration is given on p. 379 of Sylvester's extension of Poinsot's representation, where confocals to the momental ellipsoid are made to roll upon parallel planes; and now it is possible in certain corresponding herpolhodes for points of inflexion to make their appearance; the analytical and geometrical discussion of this problem has engaged the attention of de Sparre and Hess.

We mentioned at the outset that the author did not permit himself the use of elliptic functions; but apparently he could not resist the temptation of introducing them in the complete solution of Poinsot's motion, the simplicity and elegance of the representation being so great. In the separating case, when the modulus of the elliptic functions becomes unity, the introduction of the corresponding hyperbolic functions would have exhibited an analogous symmetry.

By considering the elliptic functions as defined by plane pendulum motion, some of the results in the motion of the top or gyrostat could have been exhibited by comparison with a plane pendulum; but it must be confessed that the simplicity is not maintained when we investigate the projection of the motion on a horizontal plane, without we introduce functions invented by Hermite, of a higher degree of complication.

In the discussion of precession and nutation, a simplification can be introduced by making use of the observed fact in determining the latitude, that the deviation of the axis of rotation from the axis of figure, although certainly existing, is quite inappreciable in the case of the earth; so that the axes of figure, of rotation, and of angular momentum may be taken as coincident. With this approximation the pole of the earth follows a point 90° in longitude behind the sun or moon with a certain velocity; and now the rest of the calculation of precession and nutation becomes a kinematical problem.

Chapter vii. discusses interesting and important problems of small oscillations and of bodies rolling on each other, *e.g.* of a billiard ball on the table; and chapter viii., on relative motion, is important as showing how far we are justified in applying our dynamical equations to the problems going on around us, considering that they take place on the surface of the earth, which is moving in a complicated manner in space. The corresponding elementary discussion in Maxwell's "Matter and Motion," on the ideas of relative motion, and the modification of the principles of dynamics to make them rigorous, is well worth attention at this point.

The deviation from the vertical of a body let fall down a deep mine, of a projectile from the vertical plane of fire, and the rotation of the plane of oscillation of Foucault's pendulum, are discussed as illustrations of the influence of the earth's rotation in modifying a dynamical question; but considering how slight a disturbing cause, such as a current of air, would be sufficient to mask the effect, we believe that these effects have not yet really been observed.

In Foucault's pendulum a very slight jockeying can make the thing go as we wish; while with artillery fire at long ranges the disturbing cause of deviation or drift quite overpowers any deviation due to the rotation of the earth. Theoretically, Foucault's pendulum, if set swinging in a plane through the rising moon, should continue to follow the moon; and roughly speaking, a shot fired at the rising moon should keep moving in the moving vertical plane through the moon, and would thus fall to one side of its original vertical plane of fire; in a range of twelve miles, and a time of flight of one minute, this deflection would, in the latitude of Shoeburyness, amount to about 71 yards, out of about 1000 yards observed average lateral deviation.

A few simple problems on the vibration of elastic threads and plates are given in chapter ix.; and chapter x., as already mentioned, is occupied by Prof. Donkin's contribution on Theoretical Dynamics.

Throughout the work good collections of illustrative examples are introduced, to test the student in his grasp of the principles given immediately before. If we might make a slight criticism, we should suggest the introduction of some arithmetical exercises on these problems, taken from examples in real life; for, as Sir William Thomson insists, it is from arithmetical applications that the student obtains a real grasp of dynamics; the examples given here only testing his algebraical and geometrical power.

In conclusion, we congratulate the student of mathematics at Oxford on the possession of such an admirable text-book, fully brought up to date in the latest developments.

A. G. GREENHILL.

ANNALS OF THE ROYAL BOTANIC GARDEN, CALCUTTA.

Annals of the Royal Botanic Garden, Calcutta. Vol. I. Appendix—(1) "Some New Species of Ficus from New Guinea," by George King, F.R.S., &c., Superintendent of the Royal Botanic Garden, Calcutta. (2) "On the Phenomena of Fertilization in *Ficus Roxburghii*, Wall," by D. D. Cunningham, F.L.S., &c., Surgeon-Major, Bengal Army. (Bengal Secretariat Press, 1889.)

ABOUT a dozen new species of Ficus are added here to Dr. King's valuable monograph of the figs of the "Indo-Malayan and Chinese countries," which occupies the whole of the first volume of the "Annals." It may be remembered that Dr. King proposed a modified classification of the species of *Ficus*, based upon characters indicating, in his view, the direction of evolution in the genus, beginning with a small group having pseudo-hermaphrodite flowers (*Palæomorphe*),

and ending with another small group (*Neomorphe*) remarkable for having di- or tri-androus male flowers, and the receptacles (fruit) borne in clusters, often very large, on the trunk and branches, sometimes at the very base of the trunk.

Curiously enough, although the other five groups or sections, into which King divides the genus *Ficus*, are all represented among the additional species from New Guinea, neither the oldest nor the newest is; but both are represented there by previously known species, and the *Neomorphe* by some of the most remarkable of the genus. Thus, imperfectly as the flora of New Guinea is known, there are indications of great age and variety. Noteworthy among the species figured in the present work is *Ficus hesperidiiformis*, King, belonging to the section *Urostigma*, which is characterized by having male, female, and "gall-flowers" intermixed in the same receptacles. *Ficus hesperidiiformis* resembles the familiar india-rubber tree, *F. elastica*, but the leaves are larger and the receptacles (fruit) very much larger; the ripe dry ones resembling small oranges, hence the specific name.

Dr. Cunningham's memoir on the fertilization of *Ficus Roxburghii* is an interesting and important contribution to the subject of reproduction, inasmuch as he arrives at some rather startling conclusions with regard to the plant in question.

The relations between certain insects, parasitic in the receptacles of the fig and caprifig, and in various other species of fig, and the fertilization of the flowers, has been investigated in recent times more especially by Dr. G. King, Mr. Fritz Mueller, and Count Solms; and particulars of their results, or conclusions, have been given from time to time in NATURE (vols. xxvii. p. 584, xxxvi. p. 242, and xxxix. p. 246). Nevertheless it may be well to repeat here some of the principal conditions and phenomena of the flowers of figs. In the first place it may be noted for unbotanical readers that the flowers of figs are very small and crowded all over the interior of the receptacle or fruit. Further, that the wall or substance of the receptacle is continuous and closed, except at the apex, where it is provided with a number of closely overlapping scales, rendering ingress, and egress, without eating its way, impossible to any but a very minute insect. I say, without eating its way, because much depends upon whether insects can reach the interior of the receptacles and at the same time carry pollen with them; and writers on the subject, so far as I am aware, have not considered the probabilities of the earlier visiting-insects thus opening a channel for those following. I have also, in another place, suggested the possibility of the scales at the mouth of the receptacle being loosened at the receptive period, and Mr. C. B. Clarke tells me that he has actually observed this to be the case.

The flowers are of four kinds—namely, male, female, neuter, and gall; and they are variously associated, or separated, in different species of *Ficus*. There are indeed five kinds of flowers if we include the pseudo-hermaphrodite flowers of the group *Palæomorphe*. In the cultivated fig (*Ficus Carica*), the flowers are almost invariably all female; and the male flowers of this species are borne by the "caprifig" of the south of Europe and Western Asia. Associated in the same receptacles with the male flowers, and covering the whole of the inside except a ring near the top, are the so-called gall-flowers. Structurally they are female, but instead of bearing seed they nourish the larvæ of an insect, and the perfect females of this insect are supposed to convey the pollen of the male flowers to the receptacles containing female flowers, the ovules of which are thereby fertilized. The presence of insects in figs seems to be general in the very numerous (500 perhaps) species spread all over the tropical regions of the earth; and the commonly accepted theory is that these insects, in return for the shelter and nourishment received, convey the pollen from the male to the female flowers, so that the association is mutually beneficial. At least this was the theory of Solms and Fritz Mueller. In the introduction to his monograph of the Asiatic figs, Dr. G. King says:—"The exact way in which the females are pollenized is a matter on which I cannot pretend to throw any light. I can only state the problem." Yet a little farther on he states that there can be no doubt that the insect developed in the gall-flowers in some way conveys the pollen of the males to the females in other receptacles, though he found it difficult to understand how this could be effected; and he informed the writer that he had never discovered the slightest evidence of the process, beyond the fact that seeds were formed.

At the instigation of Dr. King, Dr. Cunningham has thoroughly investigated the phenomena of fertilization in *Ficus Roxburghii*, and he arrives at the conclusion that pollen is never, or exceedingly rarely, conveyed to the female flowers, though good seed is abundantly matured.

Ficus Roxburghii is perfectly diœcious—that is, the two sexes are produced on different trees; and the fruit is borne in large clusters on the thicker branches and trunk often at the very base of the same, and extended on the ground.[1] The receptacles are similar in shape to those of the common fig, and from two to three inches in diameter, or sometimes nearly four inches; and the flowers are proportionately large, so that they are easily examined. It may be mentioned, too, that this species belongs to King's section or sub-genus *Neomorphe*, which, in our opinion, exhibits the latest stage in the evolution of the genus.

It would occupy too much space to follow Dr. Cunningham through his investigations, but it will suffice to give some extracts from his concluding remarks:—

"There can be little room for doubt that the phenomena indicate that, while the development of embryos in the female receptacles of the tree is essentially connected with the access of the insects to the receptacular cavity, it is yet normally independent of the introduction of pollen by their agency. The fact that the access of a single insect or of a pair of them only is sufficient to determine the development of ten or twelve thousand embryos, is in itself almost conclusive against the occurrence of any ordinary process of pollination. The obstacles through which a passage has to be forced ere the receptacular cavity is reached are of such nature and amount as to render it almost inconceivable that pollen should be introduced in sufficient quantity, and there is at the same time an absolute want of evidence to show that such introduction takes place. I have carefully examined very many receptacles at various periods shortly after access

[1] A photograph of a tree in fruit forms the frontispiece to the first volume of the "Annals of the Calcutta Garden."

of insects to the cavities, and have never been able to detect any evidence of general distribution of pollen over the stigmatic surface. Examination of individual flowers has given like results; in most cases it has been impossible to find any pollen within the receptacle or cavity, and in the few cases in which any was found it was represented by one or two shrivelled grains adherent to the corpses of insects. It must be borne in mind, too, that, if we accept the hypothesis that the development of the embryos is due to ordinary processes of pollination, we must assume not only that a single insect can convey many thousands of pollen-grains with it in spite of the excessive obstructions to access presented by the ostiolar plug, but that these grains are also methodically and economically distributed, for, unless each stigma were only allowed to appropriate a single grain, the amount introduced would have to be indefinitely multiplied.

"The most important evidence against the occurrence of pollination of any sort as a normal and essential event lies, however, in the fact that the embryo originates, as it does in undoubted cases of development, apart from pollination. The embryo, as a rule—for of course it is possible that pollination and normal evolution may occur in certain individual flowers—certainly arises as an outgrowth of the nucellar parenchyma, outside the embryo-sac, and not as the result of special evolution of any elements contained with in the latter. The embryo-sac up to the period of insect-access and of initial development of the embryo normally retains the characters of a simple uninucleate cell. There is no evidence of the formation of an oosphere, of synergidæ, or of antipodal cells within it, and it is only subsequent to commencing evolution of the embryo that the primary nucleus is replaced by a large number of secondary ones, which are apparently related to the elaboration of food material for the growing embryo, when it gains access to the cavity of the sac.

"But if this be so, if pollination be unnecessary, why should the access of insects be essential to the development of embryos? The phenomena presenting themselves in connection with the male flowers of gall-receptacles appear to afford a clue to answering this question. It is just as impossible for the male flowers to come to perfection—just as impossible for perfect pollen-grains to be developed without the access of insects to the gall-receptacles—as it is for embryos to be developed in female ones under parallel circumstances.

"The development of embryos in *F. Roxburghii*, then, appears normally to be an asexual process dependent on hypertrophic budding of a specialized portion of the nucellar parenchyma, and it appears not improbable that the phenomenon is not peculiar to the species, but is the rule in the case of other figs also. This, of course, requires further investigation; but in the only instance in which I have yet had time to examine the matter—in the case of *F. hispida*—there can be no doubt that it is so."

From the foregoing extracts it will be seen that Dr. Cunningham insists on two extraordinary phenomena—namely, the impossibility of the formation of pollen in the absence of insects, and the formation of embryos by budding outside of the embryo-sac instead of sexual development. As to the first, improbable as it may seem, I am assured by two or three independent observers, who have had opportunities of testing Dr. Cunningham's work, that they have arrived at the same conclusions. As to the second, the asexual formation of embryos is not so very rare an occurrence, according to Strasburger in his elucidation of polyembryony and the so-called parthenogenesis. Then as to the whole, the phenomena would seem to point to the extinction of sexuality. The points are that the development of both pollen and embryo is due to a stimulation of the tissues caused by the punctures of insects. Therefore Dr. Cunningham might with more propriety have entitled his paper "The Phenomena of Non-Fertilization." W. BOTTING HEMSLEY.

SYNONYMY OF THE POLYZOA.

A Synonymic Catalogue of the Recent Marine Bryozoa. By E. C. Jelly, F.R.M.S. (London: Dulau and Co., 1889.

THIS is a work for which all students of the Polyzoa (Bryozoa) should be grateful. It supplies an undoubted want, and will greatly facilitate the investigation of the large and interesting class with which it deals.

Synonymy is certainly not an attractive element of natural history study. Indeed, anything of less intrinsic interest cannot well be imagined, and yet it has a specific value in relation both to morphological and systematic work, and it is of the first importance that it should be carefully determined. A just and accurate synonymy is of course an essential condition of a sound nomenclature; it is a key to the actual state of knowledge, and an index to the sources in which it must be sought, which is invaluable to the student. It is also a safeguard against duplicate and delusive names.

Miss Jelly's "Synonymic Catalogue of the Recent Marine Bryozoa" fills a vacant place. There is not, so far as we know, any work which occupies the same ground. "It aims," as the author explains in her preface, "at bringing into view all the names of *published* recent Bryozoa, with as full a synonymy as may be possible."

The fossil forms belonging to recent species, and these only, are included in the synonymy. The work, which bears the marks of careful and conscientious labour, brings before the student within small compass the entire series of published Polyzoan forms belonging to the recent fauna; supplies him with a reference to the book in which each species was first described and with the name of the writer who first described it; tracks it, as it were, however disguised by variety of name, from author to author, and so in fact furnishes an index to the whole range of the systematic literature.

The value of such a guide to the student of the Polyzoa must be at once evident. It economizes his labour; it enables him to enter upon original investigation with a full knowledge of what has been already done, and it saves him from adding to the weariness and perplexity of those who may follow him by multiplying duplicate names.

Within the last few years large additions have been made to the known species of Polyzoa, the diagnosis of which is distributed to a great extent through the biological journals of Europe and America. With all the care that he can exercise the student is continually liable to overlook some paper in some obscure periodical of which perhaps he has never heard, and, as a result, to add another name to the already burthensome synonymy. In point of fact, as a matter of convenience the synonymy of each class of any extent is worthy of separate and special treatment; and such a work as Miss Jelly has now supplied should be regarded as an essential part of the apparatus of the student who devotes himself to descriptive and systematic work.

We cannot but regret that Miss Jelly has abandoned

the name of the class which has been generally adopted in England, and which commemorates the remarkable researches of an unobtrusive but most able and original worker in the province of invertebrate zoology. We have no intention of reviving the controversy on this subject, in which indeed Miss Jelly takes no part, as she does not state the grounds on which she bases her decision. The *consensus* of Continental naturalists in favour of Ehrenberg's name has no doubt had much weight with her, but the appeal to numbers is hardly likely to satisfy those who have tried the case on its merits, and arrived at a different conclusion. Of course it would be satisfactory to secure uniformity of nomenclature, if it were possible; but those who have a strong conviction that J. V. Thompson was the earliest to appreciate and define the distinctive peculiarities of Polyzoan structure, and that his name was intended to apply not merely to the zooids of a colony, but to the type of organization which they represent, can hardly consent to be parties to an absolute rejection of his claim.

The value of such works as the present depends entirely on the care and minute accuracy with which they are compiled. Miss Jelly's "Catalogue" affords abundant proof that these qualities have not been wanting in her case. That she possesses a thorough command of the literature of her subject is shown by the fulness of the synonymy, and (very strikingly) by the explanatory notes appended to many of the species. The book supplies ample evidence of intelligent and enthusiastic interest in the subject, and patient industry in dealing with it.

As to the synonymy itself, many difficult questions arise in connection with it, which clearly cannot be discussed in a work which aims at being a guide to the recorded species, and not a critical treatise. In not a few cases of supposed synonymy we should feel compelled to dissent from the conclusions arrived at, or adopted from others. But on such points the student must satisfy himself.

We may add that the book is handsomely got up, and printed in a type which, so far as clearness is concerned, leaves nothing to be desired.

Miss Jelly is to be congratulated on the completion of a very onerous task, and on the valuable contribution which she has made to the working apparatus of the student.

OUR BOOK SHELF.

Zoologische Ergebnisse einer Reise in Niederlandsch Ost-Indien. Von Dr. Max Weber. Erstes Heft. (Leiden: Brill, 1890.)

THE numerous books, memoirs, and pamphlets that have been published during the century dealing with the natural history of the Malay Archipelago have revealed to the world of science a fauna which is perhaps unrivalled for richness, variety, and general interest. But even now we are scarcely beyond the threshold of the investigation. The travels of von Rosenberg, Wallace, van Martens, Forbes, and others, and the painstaking observations and collections of many of the Dutch residents and *controleurs*, have given us a knowledge of the principal features of the ornithology and entomology of some of the more important islands, but there are still many regions of undoubted interest that have scarcely been explored at all, even by their nominal masters the Dutch. During the journey undertaken by Prof. Weber and his wife in 1888 and 1889 some of these little-known regions and islands were visited, and the results are now appearing in a series of memoirs prepared by eminent Dutch naturalists, under the editorship of the distinguished Professor of Zoology at Amsterdam.

Several interesting new forms are described in the first part; and no doubt many others will follow in the memoirs that are now in course of preparation, from Central Celebes, Flores, and the Saleyer Islands—regions that have hitherto scarcely been visited by naturalists. But the interest in Prof. Weber's results does not by any means lie exclusively in the fauna of the remote corners of the archipelago. By investigating the fresh-water fauna and the inconspicuous forms of terrestrial invertebrates of all the districts visited, he has opened to us a new chapter in the natural history of the archipelago. The memoirs on Spongillidæ by the editor, on Apterygota by Oudemans, and on the land Planaria by Loman, are most valuable and interesting contributions to our knowledge of the tropical species of these groups. Of more than special importance is the paper by the Professor and Madame Weber, "On some New Cases of Symbiosis." One of the most remarkable of those described is that of an alga belonging to the family Trentepohliaceæ symbiotic with a fresh-water sponge. This paper is in French, and contains an interesting discussion of the problems presented and the literature of the subject.

Two memoirs, in English, by Prof. Weber and by Dr. Jentinck, deal with the mammalia collected during the journey. It appears from these pages that the curious animal the sapiutan, *Anoa depressicornis*, is not confined to the northern peninsula of Celebes, as is usually stated to be the case, but may be found in favourable localities all over the island. In a long discussion on the habitat of the rare monkey *Macacus maurus*, we are told that it occurs on the Maros River and elsewhere in South Celebes, and that it should be considered to be "one more of the remarkable animals peculiar only to that island, with a continental character."

Every naturalist who reads this first part of Prof. Weber's results will look forward with interest to the publication of the memoirs that are still in course of preparation. SYDNEY J. HICKSON.

Inorganic Chemistry, Theoretical and Practical. By William Jago, F.C.S., F.I.C. (London: Longmans, Green, and Co., 1890.)

THE number of classes established according to the regulations of the Science and Art Department is now so considerable that publishers and authors alike are ready to specially cater for their needs. Messrs. Longmans, Green, and Co. have already an extensive series of "science manuals" written to meet the requirements of students taking the elementary stage of subjects as given in the Directory of the Department; and Mr. Jago's volume is one of a similar series that is in preparation to include the matter prescribed in the advanced syllabus of each subject. After the preface we are nowhere reminded of the particular aim of the book, or of the limitations under which the author has done his work; and it is worthy of note that the papers set by the Department examiners are not reprinted at the end. Leaving the particular meaning attached to the words elementary and advanced by the Science and Art Department, we may describe the volume before us as an elementary treatise on inorganic chemistry, of about 460 pages. It includes a consideration of the more common metals and their compounds, three pages concerning the periodic law, and six pages on the "causes which modify chemical action." Fluorine takes its natural place among the halogens as an isolated element, and other of the recent advances are duly noticed Some parts are very meagre, as, for example, the paragraphs

on acetylene, in which, by the way, there occurs the very objectionable expression "two volumes of carbon" in reference to the composition of the gas. The statement that "nitric acid is largely used in the manufacture of sulphuric acid" needs qualification, especially as we are told that "sulphuric acid is largely employed in the preparation of . . . nitric acid." But, on the whole, the manual is one that deserves recommendation, and will be valued by those for whose use it has been written.

We would suggest that, in the future editions that will doubtless be called for, "choke" or "after-damp" be not described as carbon dioxide, because the amount of carbon dioxide in it is very small compared with the nitrogen present; and we do not think that the examiners at South Kensington would harshly judge any student who corrected the current notion. And if the engraver of the illustrations had photographs of the apparatus supplied him, or, better still, if the blocks could be prepared mechanically from such photographs, the figures would have an appearance of genuineness which at present many of them lack. It is better to represent the apparatus used than the operation in progress, and then one avoids such unnecessary and unwise conventionalities as appear in the attempt to illustrate a brilliant combustion in a glass jar.

Arithmetical Chemistry. Part I. By C. J. Woodward, B Sc. New Edition. (London: Simpkin, Marshall, and Co., 1890.)

IN the study of chemistry there is a certain amount of arithmetical work which the elementary student must master as he progresses, and this used to be generally considered as the part in which the young pupil was most likely to fail. But now it is different, and we fear that there is rather a danger of too much stress being laid upon arithmetical exercises. In the volume before us the author proceeds by easy stages, explaining the various subjects dealt with in a sound and simple manner. We hope for the student's sake that it is intended for the teacher to select from the numerous exercises set. At the end of the volume there are "the whole of the questions in arithmetical chemistry and chemical philosophy," selected from the examination papers of five different examining bodies, for the years 1886 to 1889 inclusive. These will doubtless be useful to the teacher if used with discretion enough to prevent his students from imagining that chemistry is a branch of arithmetic.

Air-Analysis: with an Appendix on Illuminating Gas. By J. Alfred Wanklyn and W. J. Cooper. (London: Kegan Paul, Trench, Trübner, and Co., Ltd., 1890.)

THIS small volume of ninety pages is a practical guide to air-analysis, especially for sanitary purposes. The directions are plain, and multiplication of methods is avoided. Hempel's apparatus is employed. For the estimation of oxygen, nitric oxide is advised, and it is pointed out that as an excess of the gas is used it need not be pure. The authors state that, in their hands, this method has proved very accurate, and they give experimental results showing that it is to be preferred to alkaline pyrogallol or explosion with hydrogen. Directions for these latter methods are, however, included. The estimation of small quantities of carbonic oxide is performed by absorption in a cuprous chloride solution, with subsequent elimination and measurement of the gas. The analysis of coal-gas is dealt with in the appendix, and the volume concludes with some useful tables. As an addition to the treatises on special branches of analysis written by Mr. Wanklyn, either solely or jointly, this volume will be welcomed by analysts and students.

Fresh-water Aquaria: their Construction, Arrangement, and Management. By Rev. Gregory C. Bateman. (London: L. Upcott Gill, 1890.)

MR. BATEMAN says that he has always been fond of natural history, and that when he was a boy he looked forward with pleasure to the prospect of having an aquarium of his own. When this delight was experienced, he found that it had many drawbacks. These were due to the fact that he did not know how to manage his treasure. He bought or borrowed books on the subject, but was not able to obtain all the information he required. Then he tried to find out by experiment what he could not learn by reading; and as most of his attempts were in the end successful, he resolved that he would write such a book as he himself had wished for when he was making his "first blunders in aquarium matters." The present volume is the result of this decision, and there can be no doubt that it will be very cordially welcomed by many students who want just such information as the author has brought together. He writes simply, clearly, and practically, and no one who reads with moderate care what he has to say will find much difficulty in complying with the rules he lays down. He gives, also, interesting details as to the best water-plants and live stock to be kept, how and where they are to be obtained, and how they are to be maintained in health. The volume includes many illustrations.

Scenes and Stories of the North of Scotland. By John Sinclair. (Edinburgh: James Thin. London: Simpkin, Marshall, and Co. 1890.)

MR. SINCLAIR is an intelligent and lively writer, and has produced a book which may be read with pleasure by persons who have visited, or think of visiting, the scenes he describes. The work is not, in the strict sense, scientific; but it includes many passages which are, to a certain extent, of scientific interest. The subjects are: Loch Duich, Ross-shire; the Black Rock, Ross-shire; the Island of Lewis; Assynt, in Sutherland; the Caithness coast; the town of Thurso; and the Shetland Islands. Here is ample scope for fresh observation and bright description; and the author has generally made good use of his opportunities. It is to be regretted, however, that he did not, before writing of the Island of Lewis, make himself acquainted with what trustworthy archæologists have said about the great prehistoric monument at Callernish. "There is little doubt," he asserts, "that these standing stones are a monument of the ancient Druids." There is not a shred of evidence that the Druids had anything whatever to do either with these or with any other "standing stones."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Discharge of Electricity through Gases.

ON returning from abroad I find that Prof. J. J. Thomson has written to you to complain about a passage in my Bakerian Lecture, and I should like to say a few words in explanation. I am sorry if I have said anything that would seem unfair to Prof. Thomson, but I have re-read his paper, and confess that my difficulties have not been cleared away.

I shall be glad to be allowed to enter somewhat fully into the objection raised by Prof. Thomson to my remarks, as, independently of any personal question, this may help to clear up some disputed matters. The point at issue between Prof. Thomson and myself is, whether the Clausius-Williamson dissociation hypothesis forms an essential portion of the views on

the disruptive discharge which he expressed in his paper published in the *Philosophical Magazine* for June 1883. That is partly a matter of opinion, but Prof. Thomson has certainly led his readers to think that he considered the presence of free atoms before discharge as essential.

One of the principal difficulties of any theory of the disruptive discharge is the explanation of the relation between pressure and so called dielectric strength. This relation is one of the crucial points by means of which every theory must be judged. The two following passages will show how Prof. Thomson meets the difficulty:—

"Let us now apply these considerations to the case of the electric discharge. The disturbance to which the gas in an electric field is subjected makes the molecules break up sooner into atoms than they otherwise would do, and thus diminishes the ratio of the paired to the free times of the atoms of the gas; as the intensity of the electric field increases, the disturbance in some places may become so violent that in these regions the ratio of the paired to the free times approaches the value it has when the gas is about to be dissociated."

"Let us now consider what effect rarefying the gas would have upon its electrical strength. In a rare gas the mean distance between the molecules is greater than in a dense one; and if the temperature be the same in both cases, and consequently the mean velocity of the molecules the same, the ratio of the free to the paired time will be greater for the rare than for the dense gas, for the free atoms will, on an average, be longer in meeting with fresh partners. Thus the rare gas will be nearer the state in which it begins to suffer dissociation than the dense gas, and thus it will not require to be disturbed so violently as the dense gas in order to increase the ratio of the free to the paired time to its dissociation value; and thus the intensity of the field necessary to produce discharge would be less for the rare gas than for the denser one: in other words, the electric strength would diminish with the density, and this we know is the case."

It will be seen that the explanation entirely depends on the idea that free atoms exist already before discharge. In my Bakerian Lecture, I have pointed out that the existence of free ions seems inconsistent with experimental fact, and I add: "This seems to me to be fatal to J. J. Thomson's view of the disruptive discharge." This is the passage which Prof. Thomson says implies a misconception, but surely, assuming that I am right in my argument that no dissociation takes place before discharge, I am also right in saying that this is fatal to any theory which makes the relation between pressure and spark potential depend on such dissociation. It may be said, on the other side, that the idea of decomposition of molecules by the discharge, which forms so important a feature in the theory which I have explained in my Bakerian Lecture of 1884, occurs already in Prof. J. J. Thomson's paper of 1883; and that it is unfair, therefore, to condemn his views because they do not account for a feature of the discharge which has never been satisfactorily explained. A few remarks are therefore necessary to explain the relationship between Prof. Thomson's paper of 1883 and my own of the succeeding year.

The hypothesis that the discharge of electricity in gases is similar to that in electrolytes, and that each atom of a gas such as nitrogen or hydrogen carries a permanent charge, seems so obvious that it must have occurred to many who have thought about the matter; but no attempt has, until recently, been made to develop the hypothesis so as to account for the complicated phenomena of the discharge.

The credit of being the first to have done so undoubtedly belongs to Giese, who has explained by means of it a number of observed facts concerning the behaviour of flames, and of the gases rising from flames, but he has not until quite lately considered any other part of the subject. J. J. Thomson, in 1883, published his paper "On the Theory of the Electric Discharge in Gases." The hypothesis of atomic charges is not mentioned therein, and the author does not discuss the question whether or not a current of electricity in a gas consists of a diffusion of charged atoms or not. So carefully are these matters excluded, that it is difficult to avoid the conclusion that it was done intentionally, in order that the investigation may be more general, and independent of any particular theory which might in future be established.

"As the most general assumption," the electric field is supposed to consist of "a distribution of velocity in the medium whose vortex motion constitutes the atoms of the gas; the disturbance due to this distribution of velocity will cause the molecules to break up sooner than they otherwise would do." The way in which the decomposition of molecules is connected with the spark must be judged from the passages quoted above, and from those quoted by Prof. Thomson in his letter to you. The general terms in which the whole paper is expressed may increase its scientific value, but it affords no help to those who wish to form any more definite notion what an electric current through a gas consists of. If in future it should be shown that a current of electricity does *not* consist of a diffusion of charged atoms, Prof. Thomson's reasoning may still apply. I do not know whether such general considerations may be fitly described as "a theory."

After having for a number of years attempted to trace out the consequences of the electrolytic hypothesis, and discovered some method by means of which it could be definitely tested, I presented to the Royal Society, in 1884, a paper which forms the subject of the Bakerian Lecture for that year. In that paper I referred to Prof. J. J. Thomson's of the previous year, but unfortunately I was not then aware of Giese's work, and that gentleman has undoubtedly some right to complain of the way in which his researches have, till recently, been neglected by myself and others. I have never claimed that my hypothesis of atomic charges was in any way original; but I have always maintained that that hypothesis, by itself alone, does not explain much. My recent Bakerian Lecture shows sufficiently clearly that we must form much more definite notions regarding the phenomena of dissociation and the interaction between chemical and electrical forces before we can say that we have a complete theory of the electric discharge, and those who will overcome successfully all the remaining difficulties will have done much more than those who started the idea. The work of Hittorf, E. Wiedemann, Hallwachs, Warburg, Elster and Geitel, and others, has thrown so much light on many points, that the final decision as to the truth or otherwise of the theory under discussion cannot be long deferred. I have ventured to call it the "theory of electrolytic convection," which, I should say, was a sufficiently neutral and distinctive name.

ARTHUR SCHUSTER.

A Suggestion respecting the Syllabus of the Science and Art Department.

WILL you permit me to call attention to the following considerations which have occurred to myself and several of my colleagues as the result of some years' teaching experience?

(1) The syllabus of Subject VIII. (Sound, Light, and Heat), as it at present stands, is very extensive—too much so, indeed, for the majority of students to grasp in one session. This fact is tacitly acknowledged by the Department, as a student is permitted to obtain a first class in either stage by taking two only out of the three subjects.

(2) Sound and light are pretty closely related, both being forms of wave motion, and the general ideas involved in their study very similar. But between these two subjects on the one hand, and heat on the other, this connection is small, existing, indeed (so far as the Department's syllabus extends), only in the comparatively unimportant section of radiant heat. The considerations involved in dealing with specific and latent heat and with heat as a form of energy are of an utterly different character from those presented in sound or light.

(3) The syllabus of Subject VI. (Theoretical Mechanics) is also too extensive for most students to grasp in one session, including, as it does, four subjects, viz. Statics, Dynamics, Hydrostatics, and Pneumatics. And although the Department does not officially state that a student can obtain a first class with two only of these subjects, yet the papers are always arranged to admit of his doing so by taking statics and dynamics only. Thus, in the elementary stage, a candidate may answer only seven questions out of twelve, and in the advanced, eight out of twelve, and yet in each case *nine* of the twelve are confined to statics and dynamics.

The result is that teachers and students pay but scant attention to hydrostatics and pneumatics.

(4) A large number of students take physics and mechanics simply as accessories to engineering and the applied sciences. Now, to such students a knowledge of *heat* is most essential, while sound and light are quite useless. Again, though heat has but slight connection with sound or light, it has a very strong connection with hydrostatics and pneumatics. By far the most important thermal phenomena are those presented by liquids and gases, and moreover it is precisely these that an engineering

student requires to know. For how can the action of the steam-engine be properly understood without a knowledge of the principles of fluid and gaseous pressure, and of the relation between heat and work? Yet under the present arrangement the former of these constitutes a neglected part of Subject VI., while the latter comes under Subject VIII., and is associated with matter totally irrelevant.

All these considerations seem to point to the desirability of a change in the official syllabus somewhat as follows :—

(*a*) To cut out Heat from Subject VIII., making the latter consist of Sound and Light only.

(*b*) To cut out Hydrostatics and Pneumatics from Subject VI., making the latter consist of Statics and Dynamics only.

(*c*) To combine Heat, Hydrostatics, and Pneumatics into a new subject having its appropriate number. These three could then be more effectively studied than under the present system, and there would be ample matter therein to form one of the courses from September to May. The syllabus of the new subject would naturally include all the points specified by the Department as necessary preliminaries to the study of Steam (*vide* Steam syllabus, Subject XXII.), and would thus supply a specific want to all engineering students.

On the whole, it is respectfully submitted to the authorities of the Department, and others interested in the education of the people, that the proposed alteration would conduce to a more thorough and systematic study of all the subjects referred to, and be attended with benefit to students both of physics and mechanics. VOLO LEGES MUTARI.

On Last-place Errors in Vlacq.

M. M. F. LEFORT, in his account of the great Cadastre tables, contained in the fourth volume of the *Annales de l'Observatoire Impérial de Paris*, gives a list of errors in Adrian Vlacq's ten-place table of logarithms. As this one by Vlacq, or its copy by Georg Vega, is the only complete table of ten-place logarithms yet in existence, we naturally desire to make it thoroughly accurate, and therefore proceed to correct it by aid of this new information.

M. Lefort tells us that Prony, in his instructions, was expressly enjoined "not only to compute tables which shall leave nothing to be desired as to exactitude, but to make them the most vast and imposing monument of calculation that had ever been made or even conceived," and, adds M. Lefort, "this programme, so widely sketched, has been faithfully carried out." Yet, on the very same page, we are told "that Prony fixed the general limit of precision for his logarithmic tables at 12 decimals"; this although the original work by Henry Briggs had been carried to 14 places.

Thus it seems that the Cadastre tables cannot be trusted to determine the absolute accuracy of those of Vlacq whenever the figures to be rejected are between the limits 4900 and 5100, and that in no case can they serve to check the final figures in Briggs.

Having scrupulously examined, by help of my fifteen-place table, all the corrections given by M. Lefort, I here give the results, in order that the possessors of Briggs, Vlacq, or Vega may make note of them.

Among 282 last-place corrections given, I find seven to be erroneous, the logarithms in Vlacq and in Vega being right. In order to make doubly sure, I have also used my 28-place table, and here give the exact figures from the 8th to the 20th place—

Number.		Logarithm.
26188	...	322 49959 00920
29163	...	978 49968 31667
30499	...	999 50010 73882
31735	...	026 49975 27403
34182	...	883 50038 92375
34358	...	753 50011 99957
60096	...	662 49998 09339

From this we see that the Cadastre tables are inadequate to the thorough checking of ten-place logarithms; in the case of the last of these miscorrections, even the fifteen-place table is barely sufficient, and needs to be fortified by an extended calculation.

Among the 275 remaining errors, five have been imported from Briggs, and I have therefore examined them to greater length; the logarithms to the 20th place are—

Number.		Logarithm.
7559	...	453 41468 90981
8006	...	857 69086 31797
8009	...	936 63054 38960
10033	...	122 46398 29224
99926	...	031 14867 68936

Thus there are left 270 errors to be charged against Vlacq; of these no less than 96 are within the limits of inaccuracy allowed by Prony.

Near the end of the list there occurs a group of 21 (from the number 98336 to 98367) which seem to have resulted from some single running error. Now this part of the table was copied from Briggs, and we should expect these errors there; but, on turning to the original work, we find that none of his logarithms differs by more than unit in the 14th place from that of the fifteen-place table, and thus the source of the errors in Vlacq becomes mysterious.

The most feasible explanation is that the errors had been observed and corrected while the sheet was at press, and that thus all the copies of Briggs are not alike. It is probable that the very copy used by Vlacq may be preserved in some one of the libraries in the Netherlands; in such case, an inspection would set the matter at rest. EDWARD SANG.

September 27.

On the Soaring of Birds.

IN answer to Mr. C. O. Bartrum's objections in NATURE of September 4 (p. 457), I beg to refer to an article in the *Skand. Archiv. für Physiologie*, ii. 2, in which I have given a detailed account of the weighty reasons which have led me to suppose that soaring birds are able to undertake successive alterations of direction with very little loss of *vis viva*. This loss is of the same kind as that caused by the resistance of the air to the rectilinear translation.

There is, however, one fact which, in the article in the *Skand. Archiv.*, I have thought it superfluous to point out—namely, that the manœuvre of the bird is the same, and the loss of energy thereby equally the same, whether the bird turns in a calm or in a uniform wind. If Mr. Bartrum has been led to another opinion, it may be that he has not quite made out how these turnings are executed. MAGNUS BLIX.

Lund, Sverige, October 10.

Earthquake Tremors.

IF those of your readers who are interested in this subject will turn to p. 84 of the "Report on the East Anglian Earthquake of April 2, 1884," by R. Meldola and W. White (Essex Field Club special memoirs, vol. i.), they will see that at Wivenhoe a man who felt the shock of the earth movement found to his own satisfaction, by careful measurement and calculation, that the vertical displacement where he stood amounted to no less than *six feet*. How it was that any building in Wivenhoe remained standing after so tremendous an upheaval the observer did not appear to think worth considering.

ALFRED P. WIRE.

THE PROPERTIES OF LIQUID CHLORINE.

ALTHOUGH chlorine was shown by Faraday so long ago as the year 1823 to be one of the more easily condensable gases, yet, no doubt owing in a large measure to its very disagreeable nature, comparatively little has hitherto been known concerning its properties when in a liquefied state. In view of the fact that chlorine is now stored in the liquid state for the use of manufacturing chemists in a similar manner to carbon dioxide, sulphur dioxide, and ammonia, it is imperative that something more definite should be known as to the relations of liquefied chlorine to temperature and pressure. Consequently, a very complete investigation of the subject has been made by Dr. Knietsch at the request of the directors of the "Badischen Anilin- und Sodafabrik," of Ludwigshafen; and his results, of which the following is a brief account, are published in an interesting communi-

cation to the current number of *Liebig's Annalen* (Band 259, Heft 1, p. 100).

The work includes the determination of the vapour-tension of liquid chlorine at temperatures from $-88°$ C. to 146° C. (its critical point), a complete examination of its behaviour near the critical point and the determination of its specific gravity and coefficient of expansion for a range of temperature between $-80°$ and $+80°$.

Liquid chlorine generally appears to possess a yellow colour. When, however, the colour of a long column is examined, it is found to have a distinctly orange tint. The absorption spectrum does not exhibit any characteristic bands, but the blue and violet portions of the spectrum are completely absorbed, the transmitted spectrum thus consisting of the red, orange, yellow, and green.

Vapour-Tension of Liquid Chlorine below its Boiling-Point.

The apparatus used for this determination consisted of a kind of distilling flask, whose side tube was connected by means of a piece of strong-walled caoutchouc tubing with a wide manometer tube. The flask was about half filled with liquid chlorine, and was immersed in a bath also containing liquid chlorine whose temperature could at the same time be kept equal throughout, and be very finely regulated by means of a current of air driven in through a tube passing to near the bottom of the bath.

In commencing a series of determinations the chlorine in the flask was first made to boil, thereby driving out the air remaining in the apparatus. The neck was then closed by means of a caoutchouc stopper well coated with glycerine, and the open end of the manometer was allowed to dip into a vessel containing concentrated sulphuric acid. As the flask became cooled by immersing it in the cold chlorine in the bath, sulphuric acid was drawn into the manometer until it attained a height of 3–5 cm., when the caoutchouc connection was momentarily pinched while the open end of the manometer was transferred to the mercury trough. The small column of sulphuric acid thus standing above the mercury column effectually protected it from the corroding action of the chlorine. The bath was then cooled gradually, and a series of readings taken of the temperature of the bath, by means of an alcohol thermometer, and of the position of the meniscus of the mercury in the manometer. The small column of sulphuric acid was of course calculated to its equivalent height of mercury, and added to the measured height of the mercurial column. By careful use of the current of dry air the liquid chlorine of the bath was found capable of being reduced in temperature as low as $-60°$ C. The lower temperatures, down to $-88°$, were attained by mixing more or less solid carbon dioxide with the chlorine. The results obtained are given in the table at the end.

Determination of the Pressure of Liquid Chlorine from its Boiling-Point to 40° C.

The data at present existing upon this subject are very meagre and conflicting. Davy and Faraday found the pressure at 15° C. to be 4 atmospheres, whilst Niemann gives the pressure at 0° C. as 6 atmospheres, and at 12°·5 C. as 8 atmospheres. As this is a most important point in regard to the storage of liquid chlorine in metallic bottles, great pains have been taken to arrive at unimpeachable results, and as the most certain method of measuring the pressure a high column of quicksilver was employed. The apparatus consisted of a U-tube, one limb of which was narrower than the other, and prolonged upwards to a height of over 8 metres. The other and wider limb was joined at the top by means of a capillary tube to a cup, serving the purpose of a funnel for introducing the liquid chlorine. In commencing an experiment, a convenient quantity of mercury was first poured in so as to stand in the wider limb at about a quarter its height. A column of sulphuric acid was then introduced into the wider limb so as to protect the mercury, and finally the liquid chlorine was introduced through the funnel by a process of alternately warming and cooling; the cooling was effected by pouring a little liquid chlorine over a piece of cotton wrapped round the limb and evaporating it by a strong current of air. When the limb was quite full, the chlorine occupying the capillary tube was evaporated by the warmth of a small blowpipe flame, and the capillary fused up. The apparatus was then immersed, until the wider limb was covered, in a bath of liquid sulphur dioxide for temperatures up to 0°, in ice for the determination at 0°, and in water agitated by a current of air, and either cooled by ice or warmed by a small flame for temperatures up to 40°. For the comparatively higher of these temperatures it was of course necessary to pour mercury into the longer limb so as to prevent the mercury in the wider limb being driven round the bend. Complete results are given at the end, but it may be remarked in passing that the pressure at 0° is 3·66 atmospheres; and at 15°, 5·75 atmospheres.

Determination of the Pressure at Higher Temperatures.

For these yet more dangerous and difficult experiments a metal apparatus was employed, similar in principle to that just described, except that the pressures were measured by a metal gauge manometer, which had previously been completely tested and its readings verified. It was found important in these experiments not to employ too much chlorine, as owing to the immense coefficient of expansion the whole space might become full of liquid, and further heating would cause the generation of dangerously high pressures. For temperatures up to 100° a water-bath was employed, and for the higher temperatures up to the critical point 146° an oil-bath, both kept in circulation by a rapid current of air. The pressure at the critical temperature of 146° C. was found to be as high as 93·5 atmospheres.

Critical Point of Liquid Chlorine.

The critical point was determined in a separate experiment, and some very interesting results were obtained, the yellowish green colour of chlorine perhaps assisting in rendering the appearance of what has sometimes been termed the fourth state of matter between the liquid and the gaseous more distinct than usual. A hard glass tube of 8 mm. diameter was about one-third filled with redistilled dry liquid chlorine and sealed. A small thermometer, whose readings commenced at 140°, was attached to it by platinum wire, and the whole very slowly heated in a bath of vaseline. The observations were made with the naked eye, the observer being protected from any possible explosion by a thick glass plate. At 140° extremely small bubbles began to be developed throughout the mass of liquid. At 144° the hitherto sharp meniscus began to disappear, and at 145° the presence of a liquid was only evident by the more intense yellow colour and higher refractive power of the lower portion of the tube. At 146° the contents of the tube were homogeneous throughout, the critical point being attained, and the liquid converted into gas. On allowing the tube to cool slowly, the condensation always commenced below 146°, with the formation of a cloud and a fine rain of minute yellow spheres of liquid chlorine. The rain was generally apparent throughout the whole of the upper portion of the tube. Sometimes, however, the liquid meniscus again appeared without any previous manifestation of precipitation.

Specific Gravity and Expansion of Liquid Chlorine.

It is a curious fact that many gases when compressed to the state of liquid expand enormously when heated as compared with ordinary liquids, the amount of expansion sometimes exceeding that of the gas itself. Liquid chlorine is no

exception to this rule, and it was absolutely essential that its rate of expansion should be thoroughly investigated, in order that storage bottles should not be filled to a dangerous extent. For temperatures up to 36° C. a closed dilatometer of glass was employed, the long cylindrical bulb of 60 c.c. capacity and part of the stem being filled with liquid chlorine, and the remainder of the stem with chlorine gas. The whole apparatus was immersed in a long cylindrical bath. For the lowest temperature, of — 80°, the bath was filled with solid carbon dioxide. For the determination of the specific gravity at the boiling-point of chlorine, a bath of boiling liquid chlorine itself was employed, no less than three kilograms being required. Between the boiling-point and 0° the substance used in the bath was liquid sulphur dioxide. For the determination at zero powdered ice was employed, and for the higher temperatures a water-bath kept in motion by an air current. It was not possible to proceed higher than 36° with this apparatus, on account of the danger of explosion. The higher determinations were made by means of a hydrometer suspended in liquid chlorine enclosed in a tube of hard glass which was immersed in a glass water-bath heated to the required temperature.

It will be seen from the following table that liquid chlorine is indeed a very expansible substance. The coefficient of expansion at 80° is already 0·00346, nearly equal to that of gaseous chlorine, and is rapidly increasing, so that before the critical temperature of 146° is attained, the coefficient of expansion will be considerably higher than that of the gas.

Following is a table showing the pressure, specific gravity, and coefficient of expansion of liquid chlorine for every 5° of temperature from — 80° C., calculated from the formulæ derived from the experimental data obtained.

An interesting result, which is not noticed by Dr. Knietsch in his paper, is obtained on calculating the specific volume of chlorine from the determination of specific gravity at the boiling-point, — 33°·6. On dividing the atomic weight 35·5 by 1·5575, the specific gravity at the boiling-point, the number 22·8 is obtained for the atomic or specific volume of chlorine, a number practically identical with that derived by calculation from the numerous determinations of the specific volume of compounds containing chlorine.

In this respect chlorine resembles bromine and the compound radicles NO_2 and CN, which were shown by Prof. Thorpe (Journ. Chem. Soc., 1880, 382) to occupy the same volume in the free state as in combination.

A. E. TUTTON.

ELECTRICAL STORMS ON PIKE'S PEAK.

THE "Annals of the Astronomical Observatory of Harvard College," vol. xxii., contains the meteorological observations made at the summit of Pike's Peak, Colorado, at a height of 14,134 feet above sea-level. It is not remarkable that such an elevated station should be celebrated for its electrical storms, and the observers from 1874 to 1888 have recorded many interesting details in the journals respecting their physical and physiological actions.

The manifestation of atmospheric electricity by induced effects is often very strongly marked. During the passage of electrified clouds over the summit of the peak the well-known singing and buzzing noises described as an adjunct of St. Elmo's fire were heard to proceed from the telegraph wires, the exposed instruments, the instrument shelter, and the house. The sound is said to be very similar to the buzzing of bees and crackling of burning evergreens. At times the hair of the observers became upright and strongly repellent, and the same peculiar noise proceeded from it.

Some very remarkable effects are recorded on August 18, 1877:—"During the evening the most curiously beautiful phenomena ever seen by the observer were witnessed, in company with the assistant and four visitors. Mention has been made in journal of May 25 and July 13 of a peculiar 'singing' or rather 'sizzing' noise on the wire, but on these occasions it occurred in the day-time. To-night it was heard again, but the line for an eighth of a mile was distinctly outlined in brilliant light, which was thrown out from the wire in beautiful scintillations. Near us we could observe these little jets of flame very plainly. They were invariably in the shape of a quadrant, and the rays concentrated at the surface of the line in a small mass about the size of a currant, which had a bluish tinge. These little quadrants of light were constantly jumping from one point to another of the line—now pointing in one direction and again in another. There was no heat to the light, and when the wire was touched only the slightest tingling sensation was felt. Not only was the wire outlined in this manner, but every exposed metallic point and surface was similarly tipped or covered. The anemometer cups appeared as four balls of fire revolving slowly round a common centre: the wind-vane was outlined with the same phosphorescent light, and one of the visitors was very much alarmed by sparks which were plainly visible in his hair, though none appeared in the others'. At the time of the phenomenon snow was falling, and it has been previously noticed that the 'singing' noise is never heard except when the atmosphere is very damp, and rain, hail, or snow is falling."

These displays were described with the same minuteness on June 7, 1882. It was then noticed that when the finger was passed along the line the little jets of flame were successively puffed out, to be instantly relighted in the rear. An observer also found that when he approached

one of the places from which the buzzing sound proceeded it would cease, but would recommence again as soon as he withdrew two or three feet distant.

It is recorded that the "observer, on placing his hands close over the revolving cups of the anemometer where the electrical excitement was abundant, did not discover the slightest sensation of heat, but his hands instantly became aflame. On raising them and spreading his fingers, each of them became tipped with one or more cones of light nearly three inches in length. The flames issued from his fingers with a rushing noise, similar to that produced by blowing briskly against the end of the finger when placed lightly against the lips, and accompanied by a crackling sound. There was a feeling as of a current of vapour escaping, with a slight tingling sensation. The wristband of his woollen shirt, as soon as it became dampened, formed a fiery ring around his arm, while his moustache was electrified so as to make a veritable lantern of his face. The phenomenon was preceded by lightning and thunder, and was accompanied by a dense driving snow, and disappeared with the cessation of snow."

A few instances are given of convulsive muscular contraction caused by discharges. Thus, on June 23, 1887, whilst an observer was examining the iron joints around the station, from which the above-described hissing noise was proceeding, a strong electrical manifestation was felt by a twitching of the muscles of the face and hands. A violent "return shock" was experienced by the observer, who, on June 16, 1876, "whilst sitting on a rock, saw a blinding flash of lightning dart from a cloud seemingly not more than five hundred feet away, and heard a quick deafening report, and at the same time received a shock that jerked his extremities together as though by a most violent convulsion, and left lightning sensations in them for a quarter of an hour afterwards."

Among other effects previously noticed at considerable elevations above sea-level we find that on one occasion an observer felt a pain as if from a slight burn on both temples directly under the brass buttons of his cap; when he put his hands to the spots, there was a sharp crack, and all pain disappeared. A peculiar burning sensation was also often felt on the face and hands, and the scalp appeared to be pricked with hundreds of red-hot needles. A more intense action is recorded on June 9, 1882, when an observer was "raised off his feet by the action of the electricity passing through the top of his hat. Instantly snatching the hat from his head, he observed a beam of light as thick as a lead pencil, which seemed to pass through the hat, projecting about an inch on either side and remaining visible for several seconds. The top of his hat was at least two inches from his head when this fiery lance pierced him. . . . He experienced a peculiar burning or stinging sensation of the scalp for several hours afterwards."

The telegraph wires and the buildings were struck by lightning on several occasions. When a flash struck the telegraph wire on July 19, 1884, for a moment the line resembled a belt of fire, and vibrated violently for some minutes after the discharge. Frequent discharges have also been observed between the ground wire and the rocks on which it rested.

On August 12, 1879, it is recorded:—"At 5.40 p.m. a bolt of lightning went through the arrester with the report of a rifle, throwing a ball of fire across the room against the stove and tin sheathing. At 6.35 p.m. the lightning struck the wire and building at the north end where the wires come through the window and arrester, with a crash equal to any 40-pounder. It burned every one of the four wires coming in at the window into small pieces, throwing them with great force in every direction, and filled the room with smoke from the burning gutta-percha insulation. The window-sash was splintered on the outside, one pane of glass broken, and another coated with melted copper. The anemometer wires were also burnt up, and the dial burned and blown to pieces." Barometer bulbs were cracked by lightning on August 21, 1881; and on August 15, 1886, it is recorded:—"Station struck by lightning at 6.45 p.m.; shattered the west window of the dining-room, breaking four panes of glass and shivering the casing, leaving an opening between the casing and the wall; also slightly damaged the building in several places, and set fire to some articles in the storehouse, and burned several holes in the side of a tin bucket, allowing the water in it to escape."

Again, on September 7, 1883, we read:—"Lightning struck the anemometer cups, burning a round hole about half an inch in diameter in one of them. The contact spring in the dial was badly bent, and the point of contact was considerably damaged by melting. When the insulated wire passed over a nail in the side of the house, the head of the nail was melted and the wire burnt off. Inside the window, at a bend in the wire, electricity passed off into the sill, setting some paper on fire. The paper covering the battery box was ignited. Three window lights were broken. A tourist in the dining-room was badly stunned. Observer in passing from dining-room to office was severely stunned by what seemed and felt like a blow on the head. One hand swelled rather badly. The report in the house was double, and sounded like striking red-hot iron upon which cold water had just been thrown."

Some interesting observations of hail-stones are also given. The stones are said to vary in size from peas to pigeons' eggs, and many of them were conical in shape. Sometimes they consisted of soft white snow throughout, without any nucleus, and at other times they were so hard as to require a heavy blow to break them. When this was the case, the broken hail-stones presented a stratified structure, with a centre of clear ice, and concentric rings of solid and spongy ice, with an outer covering of soft snow. It is noted that in all hail-storms the fall of hail entirely ceased for about half a minute following a heavy electric discharge; after this interval, however, the fall was considerably heavier than before.

The following observations, made on October 12, 1877, have an important bearing on the subject of hail formation:—"The rotatory movement of the hail cloud could be plainly seen, and with every violent flash of lightning the passing cloud would grow perceptibly darker, indicating increased condensation. The hail formed by this cloud must have fallen about three miles below, for the wood-packers reported quite solid hail at timber line, and none above. This verifies the theory that a hail cloud can be transported laterally several miles while the ice stones are forming."

The constant crackling of hail when it reaches the earth is also referred to, and rocks are said to give forth a peculiar chattering noise, as if they were shaken by subterranean convulsions, during the occurrence of heavy hail-storms.

These instances of inductive actions manifested during thunderstorms, electrical discharges, and their relation to hailstorms might be considerably multiplied. They confirm previous observations in an intense manner, and should be of some assistance to the student of meteorological phenomena.

R. A. GREGORY.

NOTES.

THE ordinary general meeting of the Institution of Mechanical Engineers will be held on Wednesday evening, October 29, and Thursday evening, October 30, at 25 Great George Street, Westminster, by permission of the Council of the Institution of Civil Engineers. The chair will be taken at half-past seven p.m. on each evening, by the President, Mr. Joseph Tomlinson. The following papers will be read and discussed, as far as time permits:—On tube-frame goods waggons

of light weight and large capacity, and their effect upon the working expenses of railways, by Mr. M. R. Jefferds, of London (communicated through Mr. Henry J. Marten). In connection with this paper the members are invited to inspect one of the waggons which will be on view at any time during daylight on October 29 and 30, at the Victoria passenger station of the London, Chatham, and Dover Railway, where it will be standing in the siding behind the main arrival platform, by permission of the railway company. On milling cutters, by Mr. George Addy, of Sheffield. On the mechanical treatment of moulding sand, by Mr. Walter Bagshaw, of Batley.

THE annual general meeting of the Mineralogical Society will be held in the apartments of the Geological Society, Burlington House, Piccadilly, on Tuesday, November 11, at 8 p.m.

AN Exhibition, for the most part national, will be held at Lyons in 1892. With regard to electricity it will be international.

M. FLAHAULT, the eminent algologist and Professor of Botany at Montpellier, has been sent by the Minister of Public Instruction in France on a mission to Sweden, Norway, and Denmark, for the purpose of endeavouring to establish permanent relations between the Scandinavian Universities and the centres of higher instruction in France.

THE municipality of Verona gave a cordial reception to the Italian Botanical Society, which held its third annual Congress in that city from September 1–8. Prof. Arcangeli was elected President of the Society in the place of Prof. Caruel.

THE Vienna Academy commissioned Dr. G. Bukowski to make some geological investigations in Western Asia Minor at the beginning of the present year. After leaving the Khonas-Dagh, Dr. Bukowski made an excursion from Denisli to Tshoekelez-Dagh, the district lying to the north of the Tshuruksu Valley; from thence he proceeded over the Tshukúr Pass to Jorengume, and over the Davas Ovassi table-land to the foot of the Baba-Dagh. At the end of June his researches were interrupted by ill-health.

THE Geologists' Association will open its winter session with a *conversazione*, which will be held in the Library of University College, Gower Street, on Friday, November 7. Many objects of geological interest will be exhibited on the occasion.

MR. JOHN HANCOCK, the well-known naturalist, died at his residence at Newcastle-on-Tyne on Saturday, at the age of 84. Mr. Hancock was an admirable observer of bird-life, and the Museum of the Natural History Society at Newcastle has profited largely by his knowledge and enthusiasm as an ornithologist.

THE death is announced, at the age of seventy-six, of Dr. Wenzel Leopold Gruber, the eminent Professor of Anatomy at the University of St. Petersburg.

THE first series of lectures provided by the Sunday Lecture Society begins on Sunday afternoon, October 19, in St. George's Hall, Langham Place, at 4 p.m., when Prof. Silvanus P. Thompson will lecture on "Waves of Light," with illustrations and experiments. Lectures will subsequently be given by Dr. B. W. Richardson, Mr. A. Elley Finch, Dr. Andrew Wilson, Mr. Willmott Dixon, Mr. Arthur Nicols, and Sir A. C. Lyall.

A SCIENTIFIC expedition, under the auspices of the Field Naturalists' Club of Victoria, will start on or about November 15 for the Eastern Islands. Its work will occupy from ten to fourteen days. The expedition will be divided into two parties, one of which will land on Deal Island, the other on Flinders Island. A sub-committee appointed to make the necessary arrangements has reported that while there is little information with regard to Deal Island, the utility of visiting one of the Kent group, which are small, lies in the possible opportunity of determining the limits of the strictly Tasmanian and Australian fauna and flora, since the islands lie considerably nearer the Victorian than the Tasmanian coast. The greater number of members will probably proceed to Flinders Island. They will, in all probability, be able to visit Barren Island, which lies close to the southern portion of Flinders Island. Two varieties of wallaby, waterfowl, and game of various kinds appear to be plentiful, and the nature of the country seems favourable for the pursuit of different branches of natural history.

THE October number of the *Kew Bulletin* begins with a paper on an edible fungus of New Zealand (*Hirneola polytricha*, Montagne). In order that the value of this fungus as an article of food might be tested, a supply of it was recently obtained for Kew. A portion of this supply was submitted for analysis to Prof. Church, F.R.S., and a note by him on the subject is printed in the *Bulletin*. Other subjects dealt with are Mexican Fibre or Istle, a forest plague in Bavaria (*Liparis Monacha*), okro fibre (*Hibiscus esculentus*, L.), cocoa-nut butter, and soil and cultivation in Yoruba-land.

IN the one hundred and third Annual Report of the Royal Botanic Garden, Calcutta, Dr. King says that the attention of the staff during the past year was devoted chiefly to the maintenance, in as high a state of efficiency as possible, of the various departments of the garden. Special attention was given to the herbarium, and a considerable number of new species were described. The sum of 1000 rupees having been granted in order that specimens might be obtained in Burma and Assam, Dr. King was enabled to do more than usual in these provinces. Under a recent order of the Government of India this exploration will be extended. An official document relating to Dr. King's Report, and issued by order of the Lieutenant-Governor of Bengal, contains the following passage:—"The control of Indian botanical operations has been centralized in the Calcutta Gardens, and the Superintendent has been appointed Director of the Botanical Survey of India. The grants promised by the Administrations of Burma and Assam will enable collections to be made on a larger scale and more continuously. As this work will constitute a separate Department, it has been ordered that in future years a separate Report should be submitted on the subject."

THE twenty-eighth Annual Report of the Government cinchona plantation and factory in British Sikkim, by Dr. King, has been issued. At the end of the financial year 1889–90 the plantation consisted of 4,682,401 trees of various ages, and of a nursery stock amounting to 264,000 seedlings. The crop collected during the year amounted to 304,705 pounds. The products of the factory were 1833½ pounds of sulphate of quinine, and 6578 pounds of febrifuge. The whole of the quinine and the greater part of the febrifuge were manufactured by the new fusel-oil process; and, as the arrangements for working this process were quite completed during the year, the old acid and alkali method of manufacture has now been definitively abandoned. An additional year's experience of the fusel-oil process confirms Dr. King's previously expressed opinion of its complete success. The quinine turned out by it is of excellent appearance and great purity, in the latter respect comparing favourably with most of the brands of the drug of European manufacture.

THE National Association for the Promotion of Technical and Secondary Education have issued some valuable "notes" on the working of the Technical Instruction Act; and a series of "suggestions" to County Councils and other local authorities on the use of the new fund allocated to County Councils for the purposes of technical and secondary education.

THE greater part of the new number of the *Mineralogical Magazine* consists of a most careful and interesting paper, by Mr. L. Fletcher, on the Mexican meteorites, with especial regard to the supposed occurrence of wide-spread meteoritic showers. The number includes also the following papers, all of which are short:—A visit to the calcite quarry in Iceland, by J. L. Hoskyns-Abrahall; sanguinite, a new mineral, and Krennerite, by H. A. Miers; notes on Bowenite, or pseudo-jade from Afghanistan, by Major-General C. A. McMahon; on the relations between the gliding planes and the solution planes of augite, by Prof. J. W. Judd.

IT is reported from India that Mr. John Eliott, Meteorological Reporter to the Government, starts this month on tour, and will first visit Quetta and then go down the Indus to Kurrachee and Bombay, and finally make his way to Calcutta.

WE learn from *La Nature* that on September 21 Marseilles was visited by a severe thunderstorm accompanied by torrential rain and hail. The storm began about 6 a.m., and lasted 2½ hours. Everything that was in front of the shops was carried away, and the port was filled with *débris* of all kinds. Many of the hailstones were of the size of walnuts and even of fowl's eggs; several places were struck by lightning, and many animals were drowned. Such atmospheric disturbances are said to be very rare at Marseilles.

THE Agricultural Department of Bohemia has published, in a quarto volume of 138 pages, the results of the rainfall observations made in that country during the year 1889, in continuation of the work formerly undertaken by the Hydrographic Committee, under the direction of Dr. Studnička. The stations now number 707; the rainfall is measured at 6 a.m. daily, and the amount set down to the previous day. For a large number of stations the daily rainfall is entered in the tables. The yearly results are shown upon a map, by means of reference numbers to the tables and curves for each 100 mm., and the various watersheds are also shown by red outlines. The tables show the number of wet days, and the maximum daily falls at each station. This rainfall service is now one of the most complete in Europe.

THE Annual Report of the Director of the Royal Alfred Observatory, Mauritius, for the year 1888 shows that the temperature of the air was 0°·5 below the average of the last fourteen years, and below the average in every month except August and November. The greatest rainfall in one day was 4·5 inches, on March 19, on which day 1·3 inch fell in fifty minutes. The island has not been visited by a hurricane since March 21, 1879, but the Observatory continues its useful work of examining the logs of ships traversing the Indian Ocean, and synoptic charts have been prepared for eighteen days on which tropical cyclones were experienced. The upper clouds, when visible, generally travelled from the westward. The number of unusual sky glows was less than in 1887, but were observed in all months except September, October and December. There seems to be some connection between mortality from fever and rainfall; the maximum mortality occurs about two months after the maximum rainfall, and the minimum mortality about two months after the minimum rainfall. The report contains monthly rainfall values for eight stations, and results of the meteorological observations at Seychelles and Rodrigues.

FOUR interesting phenological maps of Finland appear in the *Meteorologische Zeitschrift* for September. In these, Dr. Ihne shows the date of flowering of *Ribes rubrum*, *Prunus padus*, *Syringa vulgaris*, and *Sorbus Aucuparia* in different parts of the country, by a series of zones, embracing each five days. *Ribes* and *Prunus* begin to flower earlier than the two others, and, accordingly, the zone for a given date is further north in the case of the former; their maps also present more zones. The isophanes (or lines of the same date of flowering), bordering the zones, are approximately parallel to the parallels of latitude. The regions from June 9 to 20 have more regular boundaries than those from May 26 to June 4, more equable weather having then set in. The presence of ice, and its cooling effect on water (even after melting), and so on wind, delays the time of flowering. Thus it is that islands and the land north-west of Lake Ladoga, &c., show retardation. The unequal breadth of the zones is remarkable; Dr. Ihne supposes the cause to lie in an irregular progression of the wave of heat, due to the arrangement of land and water.

A REPORT from Nicaragua states that an earthquake occurred at Granada on September 30. No damage was done, nor did any volcanic eruption of the Mombacho take place.

A GIGANTIC pendulum has been suspended from the centre of the second platform of the Eiffel Tower. It consists of a bronze wire, one hundred and fifteen metres long, with a steel globe weighing ninety kilogrammes at the end. The object is to demonstrate visibly the motion of the earth.

IN the course of archæological explorations lately carried on in the Crimea, Prof. Vasselovski found painted human bones in two graves—six skeletons in one grave, and one in another. Prof. Grempler, of Breslau, is of opinion that these graves belonged to the original inhabitants of the Crimea, the Cimmerians of Herodotus. They laid their dead on elevated spots, so that the birds might consume the flesh. When quite bleached, the skeletons were painted with some mineral pigment. Several graves containing such painted skeletons have been found in Central Asia. Only three had been previously found in the Crimea.

WE learn from the *Botanical Gazette* that the Cornell University Experiment Station is making a large and important collection of cultivated plants; collectors being sent to leading nurseries, and botanists employed in many parts of the country to collect the cultivated plants.

THE rich algological herbarium collected by the late Prof. F. Hauck, of Trieste, has been purchased by Mme. Weber van der Bosse, of Amsterdam.

THE *Victorian Naturalist* learns from Mr. Tisdall that the English foxglove has established itself on the slopes of the Stringer's Creek Valley, near Walhalla. Last season in some parts the banks were purple with them.

NAUTILUS shells are being picked up by fortunate hunters at Portland, Victoria. The *Portland Guardian* says the search after the shells is very keen, and that before daylight numbers of enthusiasts visit the beaches ready to prosecute their searches as soon as the morning breaks.

THE Museum Committee of the Leicester Town Council, in their twelfth Report, just issued, are able to give a most satisfactory account of the institution under their charge. The building of the Town Museum has lately undergone extensive repairs, and many important additions have been made to the various departments. We may note that a very ingenious method for the exhibition of coins is in use. The pulling of a lever rotates a frame—containing cards in which the coins are inserted—in such a manner that the obverse and reverse, with a full description of each coin, are shown at the will of the observer. This method has been devised by Mr. Montagu Browne, the Curator.

A VALUABLE paper, by Mr. E. Wilson, on fossil types in the Bristol Museum, has been reprinted from the *Geological Magazine* for August and September 1890. The Bristol Museum, it seems, contains 186 distinct fossil forms; and many of them "possess for the student of British palæontology a very high interest, not only on account of the remarkable nature of the fossils themselves, but also from the fact of their having been described by some of the most distinguished of palæontologists."

MESSRS. CASSELL AND CO. have issued Part 24 of their "New Popular Educator." It includes a coloured map of France.

FOUR new parts of the "Encyklopædie der Naturwissenschaften" (Breslau, E. Trewendt) have been issued. In Parts 58 and 59 of the second Abtheilung some important contributions are made to the dictionary of chemistry included in this great work. Parts 5 and 6 of the third Abtheilung contain portions of a hand-book of physics.

THE preliminary surveys for the projected Onega-White Sea Canal have been completed. The British Vice-Consul at Archangel in his last Report says that the following facts have been established. The level of the White Sea is about 15 feet higher than that of the Lake Onega; and the length of the proposed canal would be 219 versts, of which 129 versts are a natural waterway. The proposed measurements of the canal are—breadth, 63 feet; at the locks 112 feet; and along its other portions the proposed depth is 10 feet. The cost is estimated at about 7,500,000r. (£800,000), not including the expenses incurred in the construction of a port at a point on the coast of the White Sea. With the construction of the canal it is expected that the cost of transport of goods from St. Petersburg to Archangel will be diminished from 1r. per poud to 40c. The canal will afford every facility for the transport of fish from the plentiful fishing-grounds of the White Sea to St. Petersburg, and also for the transport of the mining products of Olonets. It will also be of great strategical importance in connecting St. Petersburg and Cronstadt with the White Sea. There can be no doubt, the Vice-Consul thinks, that, considering the unlimited supply of timber in the province of Olonets, and the enterprising character of the population, shipbuilding will be carried on on a large scale when the canal is constructed.

IF we were to judge by statistics alone, we should be forced to conclude that the present system of granting rewards for the destruction of wild animals in India has had little or no effect in diminishing their numbers or in decreasing the mortality caused by them. This conclusion, however, would not be in accordance with facts. The methods according to which the statistics are collected have been so much improved that no induction can safely be made from the figures available. This is pointed out in a recent Report of the Revenue Department of the Government of Madras. The Report continues :—"The experience of almost every District officer who has been some years in the country would be that the number of destructive wild animals had largely decreased with the advance of cultivation and the progress of railways, and the evidence of natives would probably be the same. There are parts of the country still where, owing to the existence of forest and difficulty of access, wild animals of prey continue to exist in large numbers, and it is the case that, owing to various causes, Europeans at all events do less now in the way of killing large game than formerly was the case. They have less time to spare from their official duties, and less money to spend. It can hardly, however, be doubted that, owing to the existence of the system of granting rewards for animals slain, native shikaris are encouraged to maintain a profession which otherwise probably they would give up from want of support, and for this reason, if for no other, the Board would not wish to see at present any change made in the system of granting rewards. It may be hoped that the construction of the East Coast Railway, and the branch from it through the heart of the Vizagapatam district to the Central Provinces, will tend in a great measure to reduce the number of wild animals in the districts where they now do very considerable damage. Cultivation and population in tracts now given up to jungle and grass will increase largely, and the need of wood for the railways will lead probably to the destruction of large areas of jungles, which now exist in tracts which should be devoted to agriculture."

NATURALISTS will read with interest a paper in *Humboldt* for September, in which Prof. Forel, of Zürich, gives the results of a visit he lately paid to Tunis and Eastern Algeria, chiefly to observe the ants there. Looking from a ship at the dreary grey wastes, and the large date-palm oasis of Gabes, one fancies all animal life must be concentrated under the palms. But really there is very little of it there, and hardly anything singular; while the sand of the desert contains, round each of the poor, small, sparse plants, a host of beetles and other insects, many of them with striking adaptations and peculiarities. Some live on excrement of camels, asses, &c., some on the plants, and some prey on other animals, big and small. In one ant-hill he found that several ants had a small brown object clinging to the lower part of an antenna; in some cases, one on either antenna. On examination, this fell off, and was found to be a small beetle, which evidently clings there as guest; it has tufts of hair, which are probably licked by the ant. The host did not seem to trouble itself about this little creature, which, by its odd post, is enabled to accompany the ant in its wanderings and changes of abode. Prof. Forel remarks on the peaceful character of the ants in that region; with few exceptions they avoid fighting, and only one ant was found capable of piercing the human skin.

THE phenomenon of globular lightning was imitated by M. Planté, it will be remembered, with his secondary batteries. It has been recently shown by Herr von Lepel (*Met. Zeits.*) that this can also be done with so-called statical electricity, obtained from an influence-machine. Two thin brass-wire points from the poles of a powerful machine being held at a certain distance from the opposite sides of an insulated plate of mica, ebonite, glass, or the like, there appear small red luminous balls, which move about, now quickly, now slowly, and are sometimes still. Even better effects were had with a glass or paper disk which had been sprayed with paraffin. Small particles of liquid or dust seem to be the carriers of the light. A slight air-current makes the spherules disappear with hissing noise. These spherules, the author remarks, are phenomena of weak tension; an increase of the tension gives a rose spark-discharge. Various interesting analogies with globular lightning are traced.

IN a long series of articles a native Japanese paper gives some interesting figures about the students of Tokio. There are 107,312 students in the whole Empire in the various colleges and other high schools (primary schools and ordinary middle schools excepted). Of this number, 38,114 represent students prosecuting their studies in the capital—that is to say, about 40 per cent. of the whole number are congregated in Tokio. Among the 38,114 students, 6,899 are domiciled in Tokio, so that the number of those coming from other localities is 31,215. The amounts which individual students spend vary from seven or eight dollars to about fifteen dollars per month. Taking the average, it may be assumed that each student spends ten dollars a month, or 120 dollars a year. Thus the total amount of money annually disbursed by these lads is a little over 3,700,000 dollars. In other words, money aggregating over three millions and a half is being yearly drawn from the provinces to the capital through this channel. The provinces receive little in return, for few of the students ever go back to their homes, their sole ambition being to remain in the capital, and there rise to eminence in some walk of life.

THE British Consul at St. Jago de Cuba, in his latest Report, refers to the disease in the cocoa-nut plantations there, and the result of the investigations into the pest made by the Academy of Sciences of Havanna. Their Report attributed the disease to a microscopic fungus of the genus *Uredo*, and stated that the

only remedy was to cut down and burn all the trees attacked. Dr. Galves, however, endeavoured at the time to convince the Academy that this was an error, and that the disease proceeded from an hemipterous insect of the genus *Coccus*, which he classified as *Diaspis vandalicus*, and afterwards Dr. Valdés Dominguez, of Baracoa, confirmed this opinion. Finally, at the end of last year, Dr. Carlos de la Torre, a member of the Academy, set all doubt at rest, and proved that the *Uredo* referred to by the Commission did not even exist in the cocoa-nut trees, and that the small stains which had been mistaken for it were normal to the plant, and existed both in the healthy and attacked trees, and that the real cause was the *Diaspis vandalicus* of Galves, together with three other species of *Coccus*. The first symptom of the disease is the appearance on the under side of the leaflets of the fronds, of small white stains, almost imperceptible. These soon attain the size of a pepper-corn, and impart a general white colour to the leaflets, which change, later on, to yellow, and finally dry up.

THE additions to the Zoological Society's Gardens during the past week include two Black-eared Marmosets (*Hapale penicillata*) from South-East Brazil, presented by Captain C. Crawford-Caffier, R.N.; an African Civet Cat (*Viverra civetta*), a Two-spotted Paradoxure (*Nandinia binotata*) from West Africa, presented by Lieut.-Colonel W. Gordon Pachett, W.I.R.; a Serval (*Felis serval*) from West Africa, presented by Mr. J. H. Cheetham, F.Z.S.; two Long-fronted Gerbilles (*Gerbillus longifrons* ♂ ♀) from Western Asia, presented by Mrs. F. A. Kitchener; two Blackcaps (*Sylvia atricapilla*), a Garden Warbler (*Sylvia hortensis*), British, presented by Mr. J. Young, F.Z.S.; three Passerine Parrots (*Psittacula passerina*) from Brazil, presented by Mr. Arthur Robottom; a Barnard's Parrakeet (*Platycercus barnardi*) from Australia, presented by Mrs. E. M. Temple; a Golden Eagle (*Aquila chrysaëtus*) from Morocco, presented by Mr. Charles A. Payton; a Snowy Egret (*Ardea candidissima*) from America, presented by Mr. H. H. Sharland; a Herring Gull (*Larus argentatus*), three Lesser Black-backed Gulls (*Larus fuscus*), British, presented by the Hon. J. S. Gathorne Hardy, M.P., F.Z.S.; two Purple Porphyrios (*Porphyrio cæruleus*) from Sicily, presented by Mr. J. I. S. Whitaker; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mrs. Wanklyn; two North African Jackals (*Canis anthus*) from North Africa, deposited; two Philantomba Antelopes (*Cephalophus maxwelli* ♂ ♀) from South Africa, three Passerine Parrots (*Psittacula passerina*) from Brazil, a Lucian's Parrakeet (*Palæornis luciania* ♂) from China, purchased; six Esquimaux Dogs (*Canis familiaris* var. 4 ♂ 2 ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on October 16 23h. 41m. 28s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 4940	—	—	23 15 9	+ 7 28
(2) G.C. 4964	—	Bluish-green.	23 20 56	+41 47
(3) 280 Schj.	8	Very red.	23 55 39	+59 44
(4) ψ_1 Aquarii	4·5	Whitish-yellow.	23 9 34	− 9 45

(8) R Lyræ	Var.	Red.	18 52 0	+43 48

Remarks.

(1) The spectrum of this nebula has not yet been recorded. It is described as "considerably bright; pretty small; round; pretty suddenly brighter in the middle."

(2) This remarkable planetary nebula was stated by Lassell to be bi-annular, consisting of a nucleus and two rings, whilst Lord Rosse observed a spiral structure. Herschel described it as "a very remarkable planetary nebula; very bright; pretty small; round; blue." The spectrum is also a remarkable one, consisting of the three ordinary lines of the nebulæ, and, in addition, a line near wave-length 470, which was first seen by Dr. Huggins. This line occurs only in this nebula, with the exception of the Orion nebula, where it has been recorded by Mr. Taylor, and is also feebly impressed in Mr. Lockyer's photograph of the spectrum. It is, however, far brighter in the planetary nebula than in the Orion nebula. It has been suggested that the line is really the blue band of carbon under such conditions that most of the light is concentrated at about wave-length 470, as is sometimes the case in the laboratory. If this be so, it ought not to be so sharply defined as the other lines, and an observation should be made with reference to this point. Other lines, especially near the carbon flutings in the green, should also be looked for.

(3) The spectrum of this star, according to the observations of Dunér, is undoubtedly a banded one, but whether it is one of Group II. or Group VI. is doubtful. The strongest band is in the red, and this is very little degraded. In the green there is another band, which is wider but not so strong. With less certainty other bands were detected in the red and yellow-green, and another "very vaguely" in the blue. The spectrum is well worth further investigation, as we are likely to learn most by a study of the apparent departures from the regular types.

(4) A star of the solar type, with fine lines (Konkoly). The spectrum should be further examined as to whether the temperature is increasing (Group III.) or decreasing (Group V.). The fineness of the lines tend to show that it is the latter.

(5) A star of Group IV. (Konkoly).

(6) The spectrum of this variable, according to Gore's Catalogue, has yet to be determined, and the forthcoming maximum of October 19 may therefore be taken advantage of. The period is about 169 days, and the magnitude ranges from 8·3–9·0 at maximum to $<$ 12·8 at minimum.

(7) This variable of Group II. will reach a maximum about October 21. The period is about 326 days, and the variation from 7·4–9·0 at maximum to $<$ 13 at minimum. Bright lines and carbon flutings should be looked for.

(8) This well-known variable of Group II. will reach a maximum about October 24. The range is small (4·3–4·6) and the period short (46 days), two conditions which appear to go together, exactly as is demanded by the collision theory of this kind of variability. Further, if that explanation be correct, it is not likely that bright lines will appear at maximum, and this may be made a test observation. A. FOWLER.

THEORY OF SOLAR RADIATION.—Mr. W. Goff has written a pamphlet in which he propounds a theory of the sun's radiation of heat. It is well known that geologists and physicists demand a much longer duration of the sun's past activity than the present estimate of the expenditure of heat would allow, supposing that there have been no unknown means of supply. Dr. Croll, in "Stellar Evolution," brings forward evidence in support of the longer periods. To account for the great disparity that exists between the results arrived at from different points of view, he assumed that the primitive nebulous mass possessed a store of energy derived from the impact of two large cold bodies moving with enormous velocities. Mr. Goff also thinks that the grounds upon which geologists and biologists found their conclusions are more certain and trustworthy than those of the physicist. He does not, however, supplement gravitational energy by energy derived from other sources, in order to account for the sun's outlay, but shows that the methods adopted for arriving at values of the amount are at fault. In his words:—"Radiant energy is a very different thing from absorbed heat, and I have endeavoured to demonstrate that its value must be considerably less. Also I have shown that the current estimates of the sun's annual loss of heat are founded entirely on an absorbed heat basis. They must, consequently, if my arguments are correct, be far in excess of what his expenditure actually is." The distinction between radiant energy and absorbed heat is clearly indicated, and it is evident that, unless the value of each is the same, the present determinations of the sun's emission of heat must be incorrect.

THE SATELLITES OF SATURN.—The micrometer measures of the satellites of Saturn made by Dr. Hermann Struve with the 30-inch Pulkova equatorial, has led to some interesting and im-

portant results. In a recent communication (*Astronomische Nachrichten*, No. 2983), the orbits of Mimas and Enceladus, and their relation to those of the other satellites, are considered. The orbit of Mimas has an eccentricity of 0·016, and an inclination of 1° 26′. The retrograde movement of the nodes, is about 1° per day, and is accompanied by a direct movement of the perisaturnium point, which is almost equal to it (− 365° and + 371° per year). The comparison of the Pulkova observations with those made at Washington (1882-86) indicates an acceleration of the mean motion of Mimas, which corresponds to a retardation in the mean movement of Tethys. Dr. Struve shows that the changes in the elements and mean motions of the two satellites may increase indefinitely, or vary between certain limits. The latter explanation is proved to be the correct one, and a discussion of the observations of Sir W. Herschel, Lassell, Marth, Newcomb, Asaph Hall, &c., leads to the conclusion that the conjunctions of Enceladus and Dione occur at the perisaturnium of the former satellite or nearly so, whilst those of Mimas and Tethys oscillate 45° about the point midway between the ascending nodes of their orbits on Saturn's equator, and perform this libration in about sixty-eight years.

The masses of Dione and Tethys inferred by Dr. Struve from the libration are respectively seven and eleven times smaller than those deduced from photometric comparisons with Titan. The result for Mimas is twenty-two times smaller than that furnished by photometry. It appears necessary to admit, therefore, that in the system of Saturn, as in that of Jupiter, either the intrinsic brilliancy of the satellites increases, or their density decreases, as the planet is approached. A knowledge of the masses of the four above-named satellites, determined photometrically and found by Dr. Struve, allows those of Enceladus and Rhea to be estimated with some probability. The following are the calculated and the hypothetical values in terms of the mass of Saturn: Mimas, 1/11,500,000; Enceladus, 1/4,000,000; Tethys, 1/767,000; Dione, 1/528,000; Rhea, 1/200,000; Titan, 1/4700. By adopting the above hypothetical values of the masses of Enceladus and Rhea, the observed and calculated values of the secular motions of the nodes and apses are found to agree in a very satisfactory manner. The spheroidal constant of Saturn has been determined as 0·0258, which differs considerably from the value 0·0223 assumed in a previous paper (*Astronomische Nachrichten*, No. 2946). This alteration obviates the necessity of giving the ring-system a sensible mass in the calculations.

A NEW COMET (*d* 1890).—A faint comet was discovered by Mr. E. E. Barnard, of the Lick Observatory, on the 6th inst. It was then situated in Capricornus.

ANTARCTIC EXPLORATION.

THE following address, on "The Objects of Antarctic Exploration," was delivered at the annual meeting of the Bankers' Institute of Australasia, at Melbourne, on Wednesday, August 27, by Mr. G. S. Griffiths, F.G.S., F.R.G.S., His Excellency the Earl of Hopetoun being in the chair.

Mr. Griffiths said,—My experience, during the four years which have elapsed since this project was first mooted in Melbourne, is that any reference to the subject is sure to be met with the query, *Cui bono?* What good can it do? What benefit can come from it? What is the object to be served by such an expedition?

In setting myself to the task of answering these questions, let me observe that it would indeed be strange if an unexplored region, 8,000,000 square miles in area—twice the size of Europe—and grouped around the axis of rotation and the magnetic pole, could fail to yield to investigators some novel and valuable information. But when we notice that the circle is engirdled without by peculiar physical conditions which must be correlated to special physical conditions within, speculation is exchanged for a confident belief that an adequate reward must await the skilled explorer. The expected additions to the geography of the region are, of all the knowledge that is to be sought for there, the least valuable. Where so many of the physical features of the country—the hills, the valleys, and the drainage lines—have been buried beneath the snow of ages, a naked outline, a bare skeleton of a map, is the utmost that can be delineated. Still, even such knowledge as this has a distinct value, and as it can be acquired by the explorers as they proceed about their more important researches, its relatively small value ought not to be admitted as a complete objection to any enterprise which has other objects of importance. Our present acquaintance with the geography of the region is excessively limited. Ross just viewed the coasts of Victoria Land, between 163° E. and 160° W. long.; he trod its barren strand twice, but on each occasion for a few minutes only. From the adjacent gulf he measured the heights of its volcanoes, and from its offing he sketched the walls of its icy barrier. Wilkes traced on our map a shore-line from 97° E. to 167° E. long., and he backed it up with a range of mountains, but he landed nowhere. Subsequently Ross sailed over the site assigned to part of this land, and hove his lead 600 fathoms deep where Wilkes had drawn a mountain. He tells us that the weather was so very clear, that had high land been within 70 miles of that position he must have seen it ("Ross's Voyage," 1278). More recently Nares, in the *Challenger*, tested another part of Wilkes's coast-line, and with a like result; and these circumstances throw doubts upon the value of his reported discoveries. D'Urville subsequently followed a bold shore for a distance of about 300 miles from 136° E. to 142° E. long.; whilst in 67° S. lat., and between 45° E. and 60° E. long., are Enderby's and Kemp's lands. Again, there is land to the south of the Horn, which trends from 45° to 75° S. lat.. These few discontinuous coast-lines comprise all our scanty knowledge of the Antarctic land. It will be seen from these facts that the principal geographical problem awaiting solution in these regions is the interconnection of these scattered shores. The question is, Do they constitute parts of a continent, or are they, like the coasts of Greenland, portions of an archipelago, smothered under an overload of frozen snow, which conceals their insularity? Ross inclined to the latter view, and he believed that a wide channel leading towards the Pole existed between North Cape and the Balleny Islands ("Ross's Voyage," 1221). This view was also held by the late Sir Wyville Thomson. A series of careful observations upon the local currents might throw some light upon these questions. Ross notes several such in his log. Off Possession Island a current, running southward, took the ships to windward (*ibid.*, 1195). Off Coulman Island another drifted them in the same direction, at the rate of eighteen miles a day (*ibid.*, 1204). A three-quarter knot northerly current was felt off the barrier, and may have issued from beneath some part of it. Such isolated observations are of little value, but they were multiplied, and were the currents correlated with the winds experienced, the information thus obtained might enable us to detect the existence of straits, even where the channels themselves are masked by ice-barriers.

Finally, it is calculated that the centre of the polar ice-cap must be three miles, and may be twelve miles, deep, and that, the material of this ice mountain being viscous, its base must spread out under the crushing pressure of the weight of its centre. The extrusive movement thus set up is supposed to thrust the ice cliffs off the land at the rate of a quarter of a mile per annum. These are some of the geographical questions which await settlement.

In the geology of this region we have another subject replete with interest. The lofty volcanoes of Victoria Land must present peculiar features. Nowhere else do fire and frost divide the sway so completely. Ross saw Erebus belching out lava and ashes over the snow and ice which coated its flanks. This circumstance leads us to speculate on the strata that would result from the alternate fall of snow and ashes during long periods and under a low temperature. Volcanoes are built up, as contradistinguished from other mountains, which result from elevation or erosion. They consist of *débris* piled round a vent. Lava and ashes surround the crater in alternate layers. But in this polar region the snowfall must be taken into account as well as the ash deposit and the lava-flow. It may be thought that any volcanic ejecta would speedily melt the snow upon which they fell, but this does not by any means necessarily follow. Volcanic ash, the most widespread and most abundant material ejected, falls comparatively cold, cakes, and then forms one of the most effective non-conductors known. When such a layer, a few inches thick, is spread over snow, even molten lava may flow over it without melting the snow beneath. This may seem to be incredible, but it has been observed to occur. In 1828, Lyell saw on the flanks of Etna a glacier sealed up under a crust of lava. Now, the Antarctic is the region of thick-ribbed ice. All exposed surfaces are quickly covered with snow. Snowfalls, fish-falls, and lava-flows must have been heaping themselves up around the craters during unknown ages. What has

been the result? Has the viscosity of the ice been modified by the intercalation of beds of rigid lava and of hard-set ash? Does the growing mass tend to pile up or to settle down and spread out? Is the ice wasted by evaporation, or does the ash-layer preserve it against this mode of dissipation? These interesting questions can be studied round the South Pole, and perhaps nowhere else so well.

Another question of interest, as bearing upon the location of the great Antarctic continent, which it is now certain existed in the Secondary period of geologists, is the nature of the rocks upon which the lowest of these lava-beds rest. If they can be discovered, and if they then be found to be sedimentary rocks such as slates and sandstones, or plutonic rocks such as granite, they will at once afford us some data to go upon, for the surface exposure of granite signifies that the locality has been part of a continental land sufficiently long for the weathering and removal of the many thousands of feet of sedimentary rocks which of necessity overlie crystalline rocks during their genesis; whilst the presence of sedimentary rocks implies the sometime proximity of a continent from the surfaces of which alone these sediments, as rain-wash, could have been derived.

As ancient slate rocks have already been discovered in the ice-clad South Georgias, and as the drag-nets of the *Erebus* and the *Challenger* have brought up from the beds of these icy seas fragments of sandstones, slates, and granite, as well as the typical blue mud which invariably fringes continental land, there is every reason to expect that such strata will be found.

Wherever the state of the snow will permit, the polar mountains should be searched for basaltic dykes, in the hope that masses of specular iron and nickel might be found, similar to those discovered by Nordenskiöld, at Ovifak, in North Greenland. The interest taken in these metallic masses arises from the fact that they alone, of all the rocks of the earth, resemble those masses of extra-terrestrial origin which we know as meteorites. Such bodies of unoxidized metal are unknown elsewhere in the mass, and why they are peculiar to the Arctic it is hard to say. Should similar masses be found within the Antarctic, a fresh stimulus would be given to speculation. Geologists would have to consider whether the oxidized strata of the earth's crust thin out at the poles; whether in such a case the thinning is due to severe local erosion or to the protection against oxygen afforded to the surface of the polar regions by their ice-caps, or to what other cause. Such discoveries would add something to our knowledge of the materials of the interior of our globe and their relation to those of meteorites.

Still looking for fresh knowledge in the same direction, a series of pendulum observations should be taken at points as near as possible to the Pole. Within the Arctic circle the pendulum makes about 240 more vibrations per day than it does at the equator. The vibrations increase in number there because the force of gravity at the earth's surface is more intense in that area, and this again is believed to be due to the oblateness of that part of the earth's figure, but it might be caused by the bodily approach to the surface at the poles of the masses of dense ultra-basic rocks just referred to. Thus, pendulum experiments may reveal to us the earth's figure, and a series of such observations, recorded from such a vast and untried area, must yield important data for the physicist to work up. We should probably learn from such investigations whether the earth's figure is as much flattened at the Antarctic as it is known to be at the Arctic.

We now know that in the past the North Polar regions have enjoyed a temperate climate more than once. Abundant seams of Palæozoic coal, large deposits of fossiliferous Jurassic rocks, and extensive Eocene beds, containing the remains of evergreen and deciduous trees and flowering plants, occur fa. within the Arctic circle. This circumstance leads us to wonder whether the corresponding southern latitudes have ever experienced similar climatic vicissitudes. Conclusive evidence on this point it is difficult to get, but competent biologists who have examined the floras and faunas of South Africa and Australia, of New Zealand, South America, and the isolated islets of the Southern Ocean, find features which absolutely involve the existence of an extensive Antarctic land—a land which must have been clothed with a varied vegetation, and have been alive with beasts, birds, and insects. As it also had had its fresh-water fishes, it must have had its rivers flowing and not frost-bound, and in those circumstances we again see indications of a modified Antarctic climate. Let us briefly consider some of the evidence for the existence of this continent. We are told by Prof. Hutton, of Christchurch, that 44 per cent. of the New Zealand flora is of Antarctic origin. The Auckland, Campbell, and Macquarie Islands all support Antarctic plants, some of which appear never to have reached New Zealand. New Zealand and South America have three flowering plants in common, also two fresh-water fishes, five seaweeds, three marine crustaceans, one marine mollusk, and one marine fish. Similarly New Zealand and Africa have certain common forms, and the floras and faunas of the Kerguelen, the Crozets, and the Marion Islands are almost identical, although in each case the islands are very small, and very isolated from each other and from the rest of the world. Tristan d'Acunha has 58 species of marine Mollusca, of which number 13 are also found in South America, six or seven in New Zealand, and four in South Africa (Hutton's "Origin of New Zealand Flora and Fauna"). Temperate South America has 74 genera of plants in common with New Zealand, and 11 of its species are identical (Wallace's "Island Life"). Penguins of the genus Eudyptes are common to South America and Australia (Wallace, "Dist. of Animals," 1309). Three groups of fresh-water fishes are entirely confined to these two regions. Aphritis, a fresh-water genus, has one species in Tasmania and two in Patagonia. Another small group of fishes known as the Haplochitonidæ inhabit Tierra del Fuegia, the Falklands, and South Australia, and are not found elsewhere, while the genus Galaxias is confined to South Temperate America, New Zealand, and Australia. Yet the lands which have these plants and animals in common are so widely separated from each other that they could not now possibly interchange their inhabitants. Certainly towards the equator they approach each other rather more, but even this fact fails to account for the present distribution, for, as Wallace has pointed out, "the heat-loving Reptilia afford hardly any indications of close affinity between the two regions" of South America and Australia, "whilst the cold-enduring Amphibia and fresh-water fishes offer them in abundance" (Wallace, "Dist. of Animals," 1400). Thus we see that to the north interchange is prohibited by tropical heat, while it is barred to the south by a nearly shoreless circumpolar sea. Yet there must have been some means of intercommunication in the past, and it appears certain that it took the shape of a common fatherland for the various common forms from which they spread to the northern hemisphere. As this fatherland must have been accessible from all these scattered southern lands, its size and its disposition must have been such as would serve the emigrants either as a bridge or as a series of stepping-stones. It must have been either a continent or an archipelago.

But a further and a peculiar interest attaches to this lost continent. Those who have any acquaintance with geology know that the placental Mammalia—that is, animals which are classed with such higher forms of life as apes, cats, dogs, bears, horses, and oxen—appear very abruptly with the incoming of the Tertiary period. Now, judging by analogy, it is not likely that these creatures can have been developed out of Mesozoic forms with anything like the suddenness of their apparent entrance upon the scene. For such changes they must have required a long time, and an extensive region of the earth, and it is probable that each of them had a lengthy series of progenitors, which ultimately linked it back to lower forms.

Why, then, it is constantly asked, if this was the sequence of creation, do these missing links never turn up? In reply to this query, it was suggested by Huxley that they may have been developed in some lost continent, the boundaries of which were gradually shifted by the slow elevation of the sea margin on one side and its simultaneous slow depression upon the other, so that there has always been in existence a large dry area with its live stock. This dry spot, with its fauna and flora, like a great raft or Noah's Ark, moved with great slowness in whatever direction the great earth-undulation travelled. But to-day this area, with its fossil evidences, is a sea-bottom; and Huxley supposes that the continent, which once occupied a part of the Pacific Ocean, is now represented by Asia.

This movement of land-surface-translation eastwards eventually created a connection between this land and Africa and Europe, and if when this happened the Mammalia spread rapidly over these countries, this circumstance would account for the abruptness of their appearance there.

Now, Mr. Blanford, the President of the Geological Society of London, in his annual address, recently delivered, advances matters a stage further, for he tells us that a growing acquaintance with the biology of the world leads naturalists to a belief that the placental Mammalia, and other of the higher forms of

terrestrial life, originated during the Mesozoic period, still further to the southwards—that is to say, in the lost Antarctic continent, for the traces of which we desire to seek.

But it almost necessarily follows that wherever the Mammalia were developed there also man had his birthplace, and if these speculations should prove to have been well founded we may have to shift the location of the Garden of Eden from the northern to the southern hemisphere.

I need hardly suggest to you that possibilities such as these must add greatly to our interest in the recovery of any traces of this mysterious region. This land appears to have sunk beneath the seas after the close of the Mesozoic. Now, the submergence of any mass of land will disturb the climatic equilibrium of that region, and the disappearance of an Antarctic continent would prove extremely potent in varying the climate of this hemisphere. For to-day the sun's rays fall on the South Polar regions to small purpose. The unstable sea absorbs the heat, and in wide and comparatively warm streams it carries off the caloric to the northern hemisphere to raise its temperature at the expense of ours. But when extensive land received those same heat rays, its rigid surfaces, so to speak, tethered their caloric in this hemisphere, and thus when there was no mobile current to steal northwards with it, warmth could accumulate and modify the climate.

Under the influences of such changes the icy mantle would be slowly rolled back towards the South Pole, and thus many plants and animals were able to live and multiply in latitudes that to-day are barren. What has undoubtedly occurred in the extreme north is equally possible in the extreme south. But if it did occur—if South Polar lands, now ice-bound, were then as prolific of life as Disco and Spitzbergen once were—then, like Spitzbergen and Disco, the unsubmerged remnants of this continent may still retain organic evidences of the fact in the shape of fossil-bearing beds, and the discovery of such deposits would confirm or confute such speculations as these. The key to the geological problem lies within the Antarctic circle, and to find it would be to recover some of the past history of the southern hemisphere. There is no reason to despair of discovering such evidence, as Dr. M'Cormack, in his account of Ross's voyage, records that portions of Victoria Land were free from snow, and therefore available for investigation; besides which their surface may still support some living forms, for they cannot be colder or bleaker than the peaks which rise out of the continental ice of North Greenland, and these, long held to be sterile, have recently disclosed the existence upon them of a rich though humble flora.

We have now to consider some important meteorological questions. If we look at the distribution of the atmosphere around the globe we shall see that it is spread unequally. It forms a stratum which is deeper within the tropics than about the poles and over the northern than over the southern hemisphere, so that the barometer normals fall more as we approach the Antarctic than they do when we near the Arctic. Maury, taking the known isobars as his guide, has calculated that the mean pressure at the North Pole is 29·1, but that it is only 28 at the South (Maury's "Meteorology," 259). In other words, the Antarctic circle is permanently much barer of atmosphere than any other part of the globe. Again, if we consult a wind chart we shall see that both poles are marked as calm areas. Each is the dead centre of a perpetual wind vortex, but the South Polar indraught is the stronger. Polarward winds blow across the 45th degree of north latitude for 189 days in the year, but across the 45th degree of south latitude for 209 days. And while they are drawn in to the North Pole from over a disk-shaped area 5500 miles in diameter, the South Polar indraught is felt throughout an area of 7000 miles across. Lastly, the winds which circulate about the South Pole are more heavily charged with moisture than are the winds of corresponding parts of the other hemisphere. Now, the extreme degree in which these three conditions—of a perpetual grand cyclone, a moist atmosphere, and a low barometer—co-operate without the Antarctic, ought to produce, within it, an exceptional meteorological state, and the point to be determined is what that condition may be. Maury maintained that the conjunction will make the climate of the South Polar area milder than that of the north. His theory is that the saturated winds being drawn up to great heights within the Antarctic must then be eased of their moisture, and that simultaneously they must disengage vast quantities of latent heat; and it is because more heat must be liberated in this manner in the South Polar regions than in the north that he infers a less severe climate for the Antarctic. He estimates that the resultant relative differences between the two polar climates will be greater than that between a Canadian and an English winter (Maury's "Meteorology," p. 466). Ross reports that the South Polar summer is rather colder than that of the north, but still the southern winter may be less extreme, and so the mean temperature may be higher. If we examine the weather reports logged by Antarctic voyagers, instead of the temperature merely, the advantage still seems to rest with the south. In the first place, when the voyager enters the Antarctic, he sails out of a tempestuous zone into one of calms. To demonstrate the truth of this statement, I have made an abstract of Ross's log for the two months of January and February 1841, which he spent within the Antarctic circle. To enable everyone to understand it, it may be well to explain that the wind force is registered in figures from 0, which stands for a dead calm, up to 12, which represents a hurricane. I find that during these 60 days it never once blew with the force 8—that is, a fresh gale; only twice did it blow force 7, and then only for half a day each time. Force 5 to 6—fresh to strong breezes—is logged on 21 days. Force 1 to 3—that is, gentle breezes—prevailed on 34 days. The mean wind force registered under the entire 60 days was 3·43—that is, only a four to five knot breeze. On 38 days, blue sky was logged. They never had a single fog, and on 11 days only was it even misty. On the other hand, snow fell almost every second day. We find such entries as these—"beautifully clear weather," and "atmosphere so extraordinarily clear that Mount Herschel, distant 90 miles, looked only 30 miles distant." And again, "land seen 120 miles distant, sky beautifully clear." Nor was this season exceptional, so far as we can tell, for Dr. M'Cormack, of the *Erebus*, in the third year of the voyage, and after they had left the Antarctic for the third and last time, enters in his diary the following remark. He says: "It is a curious thing that we have always met with the finest weather within the Antarctic circle; clear, cloudless sky, bright sun, light wind, and a long swell" (M'Cormack's "Antarctic Voyage," vol. i. p. 345). It would seem as if the stormy westerlies, so familiar to all Australian visitors, had given to the whole southern hemisphere a name for bad weather, which, as yet at least, has not been earned by the South Polar regions. It is probable, too, that the almost continuous gloom and fog of the Arctic (Scoresby's "Arctic Regions," pp. 97 and 137) July and August have prejudiced seamen against the Antarctic summer. The true character of the climate of this region is one of the problems awaiting solution. Whatever its nature may be, the area is so large and so near to us that its meteorology must have a dominant influence on the climate of Australia, and on this fact the value of a knowledge of the weather of these parts must rest.

To turn to another branch of science, there are several questions relating to the earth's magnetism which require for their solution long-maintained and continuous observations within the Antarctic circle. The mean or permanent distribution of the world's magnetism is believed to depend upon causes acting in the interior of the earth, while the periodic variations of the needle probably arise from the superficial and subordinate currents produced by the daily and yearly variations in the temperature of the earth's surface. Other variations occur at irregular intervals, and these are supposed to be due to atmospheric electricity. All these different currents are excessively frequent and powerful about the poles, and a sufficient series of observations might enable physicists to differentiate the various kinds of currents, and to trace them to their several sources, whether internal, superficial, or meteoric. To do this properly at least one land observatory should be established for a period. In it the variation, dip, and intensity of the magnetic currents, as well as the momentary fluctuations, of these elements, would all be recorded. Fixed term days would be agreed on with the observatories of Australia, of the Cape, America, and Europe, and during these terms a concerted continuous watch would be kept up all round the globe to determine which vibrations were local and which general.

The present exact position of the principal south magnetic pole has also to be fixed, and data to be obtained from which to calculate the rate of changes in the future, and the same may be said of the foci of magnetic intensity and their movements. In relation to this part of the subject, Captain Creak recently reported to the British Association his conclusions in the following terms. He says:—"Great advantage to the science of

terrestrial magnetism would be derived from a new magnetic survey of the southern hemisphere extending from the parallel of 40° S. as far towards the geographical pole as possible."

Intimately connected with terrestrial magnetism are the phenomena of auroras. Their nature is very obscure, but quite recently a distinct advance has been made towards discovering some of the laws which regulate them. Thanks to the labours of Dr. Sophus Tromholt, who has spent a year within the Arctic circle studying them, we now know that their movements are not as eccentric as they have hitherto appeared to be. He tells us that the Aurora Borealis, with its crown of many lights, encircles the Pole obliquely, and that it has its lower edge suspended above the earth at a height of from 50 to 100 miles, the mean of 18 trigonometrical measurements, taken with a base line of 50 miles, being 75 miles. The aurora forms a ring round the Pole which changes its latitude four times a year. At the equinoxes it attains its greatest distance from the Pole, and at midsummer and midwinter it approaches it most closely, and it has a zone of maximum intensity which is placed obliquely between the parallels of 60° and 70° N. The length of its meridional excursion varies from year to year, decreasing and increasing through tolerably regular periods, and reaching a maximum about every eleven years, when, also, its appearance simultaneously attains to its greatest brilliancy. Again, it has its regular yearly and daily movements or periods. At the winter solstice it reaches its maximum annual intensity, and it has its daily maximum at from 8 p.m. and 2 a.m., according to the latitude. Thus at Prague, in lat. 50° N., the lights appear at about 8.45 p.m.; at Upsala, lat. 60° N., at 9.30 p.m.; at Bossekop, 70° N., at 1.30 a.m. Now, while these data may be true for the northern hemisphere, it remains to be proved how far they apply to the southern. Indeed, seeing that the atmosphere of the latter region is moister and shallower than that of the former, it is probable that the phenomena would be modified. A systematic observation of the Aurora Australis at a number of stations in high latitudes is therefore desirable.

Whether or not there is any connection between auroral exhibitions and the weather is a disputed point. Tromholt believes that such a relationship is probable ("Under the Rays," 1283). He says that, "however clear the sky, it always became overcast immediately after a vivid exhibition, and it generally cleared again as quickly" ("Under the Rays,' 1235). Payer declares that brilliant auroras were generally succeeded by bad weather ("Voyage of Tegelhoff," 1324), but that those which had a low altitude and little mobility appeared to precede calms. Ross remarks of a particular display "that it was followed by a fall of snow, as usual" ("Ross's Voyage," 1312). Scoresby appears to have formed the opinion that there is a relationship indicated by his experience. It is, therefore, allowable to regard the ultimate establishment of some connection between these two phenomena as a possible contingency. If, then, we look at the eleven-year cycle of auroral intensity from the meteorological point of view, it assumes a new interest, for these periods may coincide with the cycles of wet and dry seasons, which some meteorologists have deduced from the records of our Australian climate, and the culmination of the one might be related to some equivalent change in the other. For if a solitary auroral display be followed by a lowered sky, surely a period of continuous auroras might give rise to a period of continuous cloudy weather, with rain and snow. Fritz considers that he has established this eleven-year cycle upon the strength of auroral records extending from 1583 to 1874, and his deductions have been verified by others.

In January 1886 we had a wide-spread and heavy rainfall, and also an auroral display seen only at Hobart, but which was sufficiently powerful to totally suspend communication over all the telegraph lines situated between Tasmania and the China coast. This sensitiveness upon the part of the electric currents to auroral excitation is not novel, for long experience on the telegraph wires of Scandinavia has shown that there is such a delicate sympathy between them that the electric wires there manifest the same daily and yearly periods of activity as those that mark the auroras. The current that reveals itself in fire in the higher regions of the atmosphere is precisely the same current that plagues the operator in his office. Therefore, in the records of these troublesome earth-currents, now being accumulated at the Observatory by Mr. Ellery, we are collecting valuable data, which may possibly enable the physicist to count the unseen auroras of the Antarctic, to calculate their periods of activity and lethargy, and, again, to check these with our seasons. But it need hardly be said that the observations, which may be made in the higher latitudes and directly under the rays of the Aurora Australis, will have the greater value, because it is only near the zone of maximum auroral intensity that the phenomena are manifested in all their aspects. In this periodicity of the southern aurora I have named the last scientific problem to which I had to direct your attention, and I would point out that if its determination should give to us any clue to the changes in the Australian seasons which would enable us to forecast their mutations in any degree, it would give to us, in conducting those great interests of the country which depend for their success upon the annual rainfall, an advantage which would be worth, many times over, all the cost of the expeditions necessary to establish it.

Finally, there is a commercial object to be served by Antarctic exploration, and it is to be found in the establishment of a whaling trade between this region and Australia. The price of whalebone has now risen to the large sum of £2000 a ton, which adds greatly to the possibilities of securing to the whalers a profitable return. Sir James Ross and his officers have left it on record that the whale of commerce was seen by them in these seas, beyond the possibility of a mistake. They have stated that the animals were large, and very tame, and that they could have been caught in large numbers. Within the last few years whales have been getting very scarce in the Arctic, and in consequence of this two of the most successful of the whaling masters of the present day, Captains David and John Gray, of Peterhead, Scotland, have devoted some labour to collecting all the data relating to this question, and they have consulted such survivors of Ross's expedition as are still available. They have published the results of their investigations in a pamphlet, in which they urge the establishment of the fishery strongly, and they state their conclusions in the following words. They say:—"We think it is established beyond doubt that whales of a species similar to the right or Greenland whale, found in high northern latitudes, exist in great numbers in the Antarctic seas, and that the establishment of a whale fishery within that area would be attended with successful and profitable results." It is not necessary for me to add anything to the opinion of such experts in the business. All I desire to say is that if such a fishery were created, with its head-quarters in Melbourne, it would probably be a material addition to our prosperity, and it would soon increase our population by causing the families of the hardy seamen who would man the fleet to remove from their homes in Shetland and Orkney and the Scotch coasts, and settle here.

In conclusion, I venture to submit that I have been able to point to good and substantial objects, both scientific and commercial, to justify a renewal of Antarctic research, and I feel assured that nothing could bring to us greater distinction in the eyes of the whole civilized world than such an expedition, judiciously planned and skilfully carried out.

QUARTZ FIBRES.[1]

BEFORE I enter upon the subject upon which I have to address you, I wish to point out that, quite apart from any deficiency on my part which will be only too apparent in the course of the evening, it is my intention to commit two faults which may well be considered unpardonable. In the first place, I shall speak entirely about my own experiments, even though I know that the iteration of the first personal pronoun for the space of one hour is apt to be as monotonous to an audience as it is wanting in taste on the part of a lecturer. In the second place, I am going almost to depend upon the motions of a spot of light to illustrate the actions which I shall have to describe, in spite of the fact that it is impossible for an audience to get up any enthusiasm when watching the wandering motion of a spot of light the result of the manipulation of a mystery-box, of which it is impossible to see the inside. These, however, are faults which are the immediate consequence of the nature of my subject.

Physicists deal very largely with the measurement of extremely minute forces, which it is of the utmost importance that they should be able to measure accurately. Now forces may be considered under two aspects. It may be that the force which is developed and which has to be measured is a twist, in which case the twisting force may be applied to the end of a wire directly, when the amount through which that wire is twisted is a measure of the twisting force. Or the force may be a direct pull

[1] Lecture delivered by Prof. C. Vernon Boys, F.R.S., on September 8, 1890, at the Leeds meeting of the British Association.

or a push, which may also be measured by the twist of a wire if it is applied to the end of a lever or arm carried by the wire.

Now supposing that the force—whether of the nature of a twist or of a pull, it does not matter which—is too small to produce an appreciable twist in the wire, it is obvious that a finer wire must be employed, but it is not obvious how much more easily a fine wire is twisted than a coarse one. If the fine wire is one-tenth of the diameter of the coarse one, we must multiply ten by itself four times over in order to find how much more easily twisted it is, and thus obtain the enormous number 10,000; it is 10,000 times more easily twisted than the coarse one. Thus there is an enormous advantage in increasing the minuteness of the wire by means of which feeble twisting or pulling forces are measured. But if the delicacy of the research is such that even the finest wire which can be made is still too stiff, then, even though with such wire, which is somewhere about the thousandth of an inch in diameter, forces as small as the millionth part of the weight of a single grain can be detected with certainty, the wire is of no use; and as wire cannot be made finer, some other material must be used. Spun glass is fine and strong, and is still more easily twisted than the finest wire, but it possesses a property somewhat analogous to putty. When it has been twisted and then let go, it does not come back to its old place, so that though it is much more largely twisted than wire by the application of a force, it is not possible with accuracy to measure that force. There is, or rather I should say there was, no material that could be used as a torsion thread finer than spun glass; and therefore physicists use instead a fibre almost free from torsion. A single thread of silk as spun by the silkworm is taken and split down the middle, for it is really double, and one half only is used. This is far finer than spun glass, and being softer in texture, it is much more easily twisted. Silk is ten thousand times more easily twisted than spun glass. So easily twisted is silk that in the majority of instruments the stiffness of the silk is either of no consequence at all, or at any rate it only produces but the slightest disturbing effect. Now if it is necessary to push the investigation further still by the continued increase in the delicacy of the apparatus, silk itself begins to prevent any progress. Silk has a certain stiffness, but if that were always the same it would not matter; but then it possesses that putty-like character of spun glass, but in a far higher degree; it is affected by every variation of temperature and moisture, and any really delicate measures are out of the question when silk is used as the suspending fibre.

This, I believe, is a fairly accurate account of the state of the case three years ago. At that time I was improving, or attempting to improve, a certain class of apparatus of which I shall have more to say presently, and I was met by the difficulty that a greater degree of delicacy was required than was possible with existing torsion threads. Silk would have entirely prevented me from reaching the degree of delicacy and certainty in this instrument that I hope to show this evening that I have attained.

Being then in this difficulty, I was by good fortune and necessity led to devise a process which I propose at once to show you. I shall not describe the preliminary experiments, but simply describe the process as it stands. There is a small cross-bow held in a vice, and a little arrow made of straw with a needle point, and I have here a fragment of rock crystal which has been melted and drawn into a rod. It requires a temperature greater than that developed in any furnace to melt this material so that it may be drawn out. If the arrow, which also carries a piece of the quartz rod, is placed in the bow, and if both pieces are heated up to the melting-point and joined together, and then the arrow is shot, a fibre of quartz is drawn—that is to say, it is drawn if there is not an accident.

The arrow has flown, and there is now a fibre, not very fine this time, which I shall hand to our President. At the same time I can pass him a piece of much finer fibre, made this afternoon, which shows (and this is a proof of its fineness) all the brilliant colours of the spider line when the sun shines upon it, but with a degree of magnificence and splendour which has never been seen on any natural object.

The main features of these fibres are these. You can make them as fine as you please; you can make them of very considerable length; you can make pieces 40 or 50 feet long, without the slightest trouble, at almost every shot. Even though of that great length, they are very uniform in diameter from end to end, or, at any rate, the variation is small and perfectly regular. The strength of the fibre is, I think I may safely say, something astonishing. Fibres such as I have in use at the present time in an instrument behind me are stronger than ordinary bar steel: they carry from 60 to 80 tons to the square inch. That is one of their most important features, for this reason—that on account of their enormous strength you can make use of very much finer fibres than would be possible if they were not so strong; and I have already explained the importance of the fineness of the fibre when delicacy is of the first importance.

As to the diameter of these fibres, I have said they can be made as fine as you please. I shall not trouble you with a large number of figures, but one or two may probably be interesting to those who are in the habit of using philosophical apparatus. In the first place, a fibre a great deal finer than a single fibre of silk—that is, one five-thousandth of an inch in diameter—will carry an apparatus more than thirty grains in weight. I have in one of the pieces of apparatus which I shall use presently a fibre the fifteen-thousandth of an inch in diameter. That is, so fine that if you were to take a hundred of them and twist them into a bundle you would produce a compound cable of the thickness of a single silkworm's thread. I do not mean the silk used for sewing that is wound on a reel, because that is composed of an enormous number of silk threads; but a single silkworm's thread as it is wound from the cocoon, and that fibre is at the present time carrying a mirror the movements of which will presently be visible in all parts of this large room.

But that is by no means the limit of the degree of fineness which can be reached. A fibre the fifteen-thousandth of an inch in thickness is quite a strong and conspicuous object. You may go on making them until you cannot see them with the naked eye. You may go on following them with the microscope until you cannot see them with the microscope—that is to say, you cannot find their end—they gradually go out. The ends are so fine that it is impossible ever to see them in any microscope that can be constructed, not because the microscopes are bad, but because of the nature of light. But that is a point upon which I shall not say more this evening. It has been estimated that probably the ends of some of these are as fine as the millionth part of an inch—I do not care whether they are or whether they are not, because they can never be seen and never be used—but certainly the hundred-thousandth of an inch is by no means beyond the limit which can be obtained. As these large numbers of hundreds of thousands and millions are figures which it is impossible for anybody thoroughly to realize, I may for the purpose of illustration say that, if we were to take a piece of quartz about as big as a walnut, and if we could draw the whole of that into a thread one hundred-thousandth of an inch in diameter—threads which can certainly be produced—there would be enough to go round the world about six or seven times.

These quartz fibres, on account of their fineness, are eminently capable of measuring minute forces—that is to say, they would be capable if they were free from that putty-like quality which I have described as making spun glass useless. Now, experiments made both in this country and in Australia show that to a most extraordinary degree they are perfectly free from that one fault of spun glass.

The number of useful properties of quartz that has been melted is so great that I can merely take, in a more or less disjointed way, one or two; and I propose, in the first place, to say something which, I think, may be especially interesting to chemists, and, perhaps, to our President. I should like to ask experimental chemists what they would think of a material which could be drawn into tubes, blown into bulbs, joined together in the same way that glass is joined, drawn out, attached to a Sprengel pump, sealed off with a Sprengel vacuum, which would be transparent, which would be less acted upon than glass by corrosive chemicals, and which, finally, at the point at which platinum is as fluid as water, would still retain its form. Here is such a tube with a bulb blown at the end. I have found that it is possible to make tubes (though it cannot be done in the ordinary way, as with glass) and to blow bulbs with quartz, and that they have this advantage which glass does not possess—namely, that it is almost impossible to crack them by the sudden application of heat.

Then there is another property which quartz fibres and rods possess which I shall be able to show only imperfectly—namely, the power of insulating anything charged with electricity under conditions under which in general insulation is impossible. You now see upon the screen an electroscope, the leaves of which were charged at noon, and they are still divergent, but not to a very great extent, because they have suffered from un-

avoidable shaking during the day. The point to which I specially wish to refer is this. In electroscopes and all electrostatic apparatus one puts in a dish of sulphuric acid, which is an abomination, in order to keep the atmosphere dry. I have in this electroscope such a dish, but it is filled with water in order to keep the atmosphere moist. Experiments carefully made, using the same box—everything the same—except that in one case the insulating stem was made of quartz, and in the second case it was made of the best flint glass, well washed, of the same shape and size, show that, if the atmosphere is perfectly dry, the electricity escapes from both at the same rate; but that, if the atmosphere is perfectly moist, the electricity escapes from the leaves insulated by the clean-washed flint glass only too quickly; whereas, from the leaves insulated by the quartz, the rate is identically the same as it was in either case when the atmosphere was perfectly dry.

I have said that these fibres are uniform in diameter, and fine and smooth and strong, and that they glisten with all the colours of the spider web, but that they are far more brilliant. It was naturally rather a curious point to note what a spider would do if by any chance she should find herself on such a web, and now that I am dealing with live and wild animals which cannot possibly be trained the conditions are such as to render the success of an experiment entirely a matter of chance. However, I propose to make use of the spider as a test of the very great smoothness and slipperiness of one of these fibres. There are here three little spiders which have been good enough, since they came to Leeds, to spin upon these little wooden frames their perfect and beautiful geometrical webs. I have succeeded in placing one of these frames in the lantern without disturbing the spider, which you can now see waiting upon her web. I must now, without disturbing the peace of mind of the spider, carry her to a web of quartz; and therefore it is necessary that the spider should be fortunate enough to catch a fly. Now, instead of bringing a fly I will make an ordinary tuning-fork buzz against the web. She immediately pounces upon the imaginary fly, and thus I can without frightening her place her upon the quartz fibre. Unfortunately this spider has slipped and has got away, but with another I am more successful. I intended to show that the small and common garden spider could not climb the quartz fibre, but for some reason this spider is able to get up with difficulty; however I shall not spend any more time upon this experiment.

I shall now at once speak about the instrument which actually led me to the invention of the process for making quartz fibres. This, which I have called a radio-micrometer, is an instrument of very great delicacy for measuring radiant heat from such a thing as a candle, a fire, the sun, or anything else which radiates heat through space.

The radio-micrometer which I wish to show this evening is resting upon a solid and steady beam, and as usual its index is a spot of light upon the scale. You see that that spot of light is almost perfectly steady. Now the heat that I propose to measure, or rather the influence of which I intend to show you, is the heat which is being radiated from a candle fixed in the front of the upper gallery some 70 or 80 feet from the instrument; and in order that you may be sure that the indication of the instrument is due to the heat from the candle, and not to any manipulation of the apparatus on the beam, I shall perform the experiment as follows. None of the apparatus at this end of the room will be touched or moved in any way; but by a string I shall simply pull the candle along a slide up to a stop, at which position it will shine upon the sensitive part of the radio-micrometer. Instantly the spot of light darts along the scale for a distance of ten feet, and then after leaving the scale it comes to rest upon the face of the balcony five or six seconds after it began to move. Now if the candle is allowed to move back through about a foot, you will see that the instrument will cool down at once—it is at present suffering from the heat which falls upon it from the distant candle; but it will cool down at once, and the index will go back to its old place. It is very nearly at its old place now. I will now let the candle shine upon it again. The index at once goes on to the balcony as before, and now that the candle is moved away again, the index has assumed its old place upon the scale.

That really shows that we have here the means of measuring heat with a degree of delicacy, and also with a degree of certainty, ease, and quickness, which has never yet been equalled. It is probable that the measure which I have given of the degree of delicacy that I have reached in my astronomical apparatus—namely, that the heat of a candle more than two miles away can certainly be felt—will not seem so absurd now that you have seen this less perfect apparatus at work, as it does to people whose experience is limited by the thermopile or their senses.

You can now see the spot of light; it is perfectly quiet in its old place. I wish to show you that this instrument is unlike those which are ordinarily used for this purpose. All the heat, the very considerable heat, due to this electric arc lamp, is actually falling on the instrument, but not upon its sensitive surface, and there is no indication. There are a large number of people in the room—it does not feel the heat from them. Stray heat which it is not meant to feel—which is not in the line along which it can see, or feel—has no influence upon it. When the candle was moved to the place to which it was looking, it felt the heat, and you saw the movement of the index. What is perhaps more important than all is, that it is an instrument which does not even feel the influence of a magnet. I have here a magnet, and on waving the magnet about near the instrument there is no movement of the index at all; it does not dance up and down the scale, as it certainly would do in the case of a galvanometer, because this magnet would affect a galvanometer at the other end of the room. We have then a degree of sensibility which is certainly not easily developed in any other way. I must except, however, the instrument which Prof. Langley of America has recently brought to a great state of perfection. I am unable to state, from want of information, whether his instrument is as sensitive as the one I have just shown, but whether it is or is not as sensitive it certainly cannot compare with this in its freedom from the disturbing effects of stray heat falling upon it, or of the magnetic or thermo-electric disturbances which give so much trouble where the galvanometer is employed.

Now this apparatus I was recently using in some astronomical experiments on the heat of the moon and the stars. As these experiments could only be made with an instrument such as this, possessing extreme sensibility and freedom from extraneous disturbances, and as this instrument is both the cause of the discovery and the first result of the application of quartz fibres, I have thought it well to repeat a typical experiment upon the moon's heat, but, like Peter Quince, I am in this difficulty. As he said, "There is two hard things, that is to bring the moonlight into a chamber." In fact, at the present time the moon has not risen, and if it had we should not be much better off. Peter Quince proposed that they should in case of moonlight failing have a lanthorn and a bunch of thorns. That no doubt was sufficient for the conversation of Pyramus and Thisbe, but that would not do for the purpose of showing the variation of radiation from point to point upon the moon's surface, and as that is the experiment which I now wish to show—an experiment which this instrument enables one to make with the greatest ease and certainty—it is necessary to have something better than a lanthorn and a bunch of thorns. Therefore I have been obliged, as the moon is not available, to bring a moon. Now this moon is a real moon; it is not a representation; it is not a slide; it is a real moon, and it is made by taking an egg-shell and painting it white. That egg-shell is now placed upon a stand, and is illuminated by the sun—that is, an electric light—and in order that the moon may be visible the room must be darkened. The moon is now shining in the sky. An image of the moon is cast by means of a concave mirror upon a translucent screen. There is in addition another mirror which throws a small image of the same moon upon the radio-micrometer. There is one more thing to explain. There is upon the screen a black spot which represents the sensitive surface of the radio-micrometer. That bears the same proportion to the moon which you see on the screen as the sensitive surface of the radio-micrometer bears to the image of the moon that is cast upon it. Now the two mirrors are arranged to move by clockwork, so as to make the two images travel at proportional rates. The moon is travelling with the dark edge foremost, and now that the terminator of the moon has come upon the sensitive surface, the heat is felt and the deflection of the instrument is the result. Now as the moon is gradually travelling through the sky, the radiation is slowly and steadily increasing, because the radiation from the moon gets greater and greater, as the point at which the sun is shining vertically—that is, a point at right angles with the terminator—is approached; it is here a maximum, and then it falls back, and as soon as the moon has gone off the instrument, you will see the index fall back almost suddenly. But there is something more. This moon in one respect is better than the other moon. At the present time it represents the moon nineteen days old, a moon, that is to say, which is waning, and which goes through the sky

with its dark edge foremost. The clockwork will now bring the moon back again, and convert the nineteen-day moon into a nine-day moon, one in which the bright edge goes forward. What I want you to notice, and it will be perfectly evident, is this, that the spot of light will now go up the scale suddenly, will then rise to a maximum position, and will then fall slowly until the terminator is reached, which proves that in the former case the slow rise and sudden fall, or the present sudden rise and slow fall was not a peculiarity of the instrument, but was due to the fact that the different points of the moon radiated in the manner which I have stated. There is one point which, as the moon has now left the instrument, I should like to show; that is, that it is a real moon and not a mere slide. That is shown by gradually moving the sun round. Now it is at right angles to the line of view, and we have got the half moon. As it goes round, the moon continues waning, appearing more like a new moon, and at last we have an eclipse of the sun, which may be annular if the proportions of the apparatus are properly arranged.

I wish now to make a few statements as to the delicacy of apparatus that can be made with the help of quartz fibres. I would wish you most distinctly to understand that it is not sufficient to go into a shop and buy apparatus as it is now made, replace the silk by quartz, and to suppose you can get a degree of delicacy such as I have shown you. That is not sufficient. If you take out the silk and put in a quartz fibre the apparatus will be much improved, and you can then increase its delicacy. You will then escape the troubles due to silk; but one after the other a new series of disturbances will appear, and anything like ultimate, extreme and minute accuracy will still seem out of the question. Now it has been my business to eliminate one by one these disturbing influences. I will not weary you with a description of them all, and the methods by which they may be certainly provided against. These disturbing causes, which at the present time with instruments carrying a silk fibre are not even known to exist, or if known to exist, are practically of no consequence whatever, come one by one into prominence, when you attempt to push the delicacy of your apparatus to the extent that I have reached in the home-made apparatus which I have here this evening. I do not propose to give more than one illustration, and as this is one which I found out by accident, and which at the time very much annoyed me, I imagine that it may be of interest to explain the circumstances under which this was observed.

In the experiments I made on the heat of the moon and the stars it was necessary to determine to what degree of delicacy the apparatus could be brought—that is to say, to determine what deflection would be produced by a known and familiar source of radiation. For this purpose the source of heat that I used was a common candle, placed sufficiently far off to produce a convenient deflection. I began by placing the candle about 100 yards away, but I was obliged to place the candle at a distance of 250 yards. At that distance I could not conveniently at night turn the shutter on and off with a string. Therefore I adopted the more simple and practical plan of asking my niece to stand at the top of the hill and to pull the string when I gave the signal. The signal was nothing more nor less than my saying the word "on" or "off," so that without moving I could observe the deflection due to the heat of the candle at that distance. Those were the circumstances, but when I shouted "on," before the sound could have reached my niece at the top of the hill, the spot of light had been driven violently off the scale. This seemed as if, as I suspected at the time, one of my little eight-legged friends had got inside the apparatus, and feeling the trembling due to the sound, struck forward, as the diadema spider is known to do, and tried to catch the thing that was flying by. But further experiments showed that this was not the case. It happened that the sound of my voice was just that to which the telescope tube would respond. It echoed to that note, the instrument felt the vibration of the air, and that was the result.

In order to show that an instrument will feel the motion in the air under the influence of sound, I have arranged an experiment of the simplest possible character. I should say that the first instrument of this kind was made many years ago by Lord Rayleigh; but I feel sure that even he would not be prepared for the delicacy to which apparatus on this principle can be brought. It simply depends upon this familiar and well-known fact. A card or a leaf allowed to drop through the air does not fall the way of the least resistance—that is, edgeways—but it turns into the position of greatest resistance, and falls broadside on, or overshoots the mark, and so gets up a spin.

Supposing you take a little mirror suspended at an angle of 45° to the direction of the waves of sound, the instant sound-waves proceed to travel, that mirror turns so as to get into such a position as to obstruct them. The mirror that I have for this purpose weighs about the twentieth part of a grain, and the fibre on which it is suspended is about the fifteen-thousandth part of an inch in diameter. The mirror is so small and light that the moment of inertia is a two-hundredth part of that which people ordinarily call the minute and delicate needle of the Thomson mirror-galvanometer. With a fibre only a few inches long, there is no difficulty in getting a period of oscillation of ten or eleven seconds. When the light from the lamp is reflected and falls upon the scale, as it will be in a minute, then a movement of the light from one of those great divisions to the next—that is, a movement of three inches—will correspond to a twisting force such as would be produced by pulling the end of a lever an inch long with a force of a thousand-millionth part of the weight of a grain. It would be easy to observe a movement ten or a hundred times less. My difficulty now is that it is impossible to speak and at the same time to keep that spot at rest, because the instrument is arranged to respond to a certain note. This is not the predominating note of my voice, but since the voice, like all other noises as distinguished from pure musical sounds, consists of a great number of notes, every now and then the note to which the instrument is tuned is sure to be sounded, and then it will respond. Therefore, while I am speaking it is impossible to keep the spot of light at rest. However, in order to show that the instrument does respond to certain notes, even if feeble, with a degree of energy and suddenness which I believe would never be expected, I shall with these small organ pipes sound three notes. But I must explain beforehand what I am going to do, as the sound of my voice will spoil the experiment. I shall, standing as far away as I can get from the instrument, first sound a note that is too high; I shall then sound a note that is too low; and then I shall sound the note to which the instrument is tuned. I must ask everyone during this experiment to be as quiet as possible, as the faintest sound of the right sort will interfere with the success of the experiment. The first two notes sounded loudly produced no result, while the moment the right note was heard the light went violently off the scale and travelled round the room. When this little organ pipe was blown at the farthest end of the room this afternoon, it drove the light off the scale, almost as violently as it did just now.

[The Cavendish experiment of observing the attraction due to gravitation between masses of lead was then explained; and the actual experiment, performed with apparatus no larger than a galvanometer, in which the attracting masses were two pounds and fifteen grains respectively, in which the beam was only about five-eighths of an inch long, and in which the total force was less than one ten-millionth of the weight of a grain, was then shown. The actual deflection on the scale was rather more than ten feet, and eighty seconds were required for the single oscillation. With this apparatus forces two thousand times as small could be observed, though the fibre is, in comparison with others that were made use of, exceedingly coarse. Forces equivalent to one million-millionth of the weight of a grain were stated to be within the reach of a manageable quartz fibre.]

Now that I have shown all that my limited time has permitted me, I wish finally to answer a question which is frequently put to me, and which possibly some in the room may have asked themselves. The question may be put broadly in this form: "These fibres no doubt are very fine, and very wonderful, but are they of any practical use?" This is a question which I find it difficult to answer, because I do not clearly know what is meant by "practical use." If by "a thing of practical use" you mean something which is good to eat or to drink, or if you mean something which we may employ to protect ourselves from the extremes of heat or cold or moisture, or if you mean —and this is a point which those who have studied biology will perhaps appreciate more than others—something which may be made use of for the purpose of personal adornment; if that is what you mean by "practical use," then with the exception of the possibility of being able to weave garments of an extraordinary degree of fineness, softness, and transparency, quartz fibres are of no "practical use." But if you mean something which will enable a large and distinguished body of men to do that which is most important to them more perfectly than has been possible hitherto—I allude of course to the experimental philosopher and his experimental work, which after all has laid the foundations upon which so much that is called practical

actually is built—if this is what you mean, then I hope that the few experiments which I have been able to show this evening are sufficient to prove that quartz fibres are of some practical use; and they have served this additional purpose—with what success I am unable to say—they have provided a subject for an evening lecture of the British Association.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 1.—The Right Hon. Lord Walsingham, F.R.S., President, in the chair.—The Rev. Dr. Walker exhibited, and read notes on, a long and varied series of *Crymodes exulis*, collected in June and July last in Iceland. In reply to a question by Lord Walsingham as to whether all the forms referred by Dr. Walker to *Crymodes exulis* had been identified as belonging to that species, Mr. Kirby said the species was a very variable one, and that several forms had been described from Labrador and Greenland. Mr. South stated he believed that most of the forms had been described by Dr. Staudinger.—Dr. D. Sharp, F.R.S., exhibited a specimen of *Ornithomyia avicularia*, L., taken near Dartford, to which there were firmly adhering—apparently by their mandibles—several specimens of a mallophagous insect. He also exhibited specimens of fragile Diptera, Neuroptera, and Lepidoptera, to show that the terminal segments in both sexes might be dissected off and mounted separately without the structures suffering from shrivelling or distortion.—Mr. G. F. Hampson exhibited a series of *Erebia melas*, taken in July last, in the Austrian Alps (Dolomites), by Mrs. Nicholls. Captain Elwes observed that this species was abundant in the Pyrenees, but he had never been able to obtain specimens from any other part of Europe; and that it had been left to an English lady to first take a species of *Erebia* new to these Alps. He added that the species only frequented very steep and stony slopes on the mountains, so that its capture was attended with difficulty.—Mr. McLachlan, F.R.S., exhibited specimens of an extraordinary Neuropterous larva found by Mr. B. G. Nevinson in tombs at Cairo. He said that this larva had been assigned to the genus *Nemoptera* by Schaum, and Roux had previously described and figured it as an abnormal apterous hexapod under the name of *Necrophilus arenarius*. Mr. Nevinson supplemented these remarks with an account of his capture of the specimens in the Egyptian tombs.—Mr. G. T. Baker exhibited species of the genus *Boarmia* from Madeira; and also melanic varieties of *Gracilaria syringella* from the neighbourhood of Birmingham.—Mr. W. F. H. Blandford exhibited and remarked on specimens of *Dermestes vulpinus*, a wood-boring beetle, which had been doing much damage to the roofs of certain soap-works in the neighbourhood of London.—Mr. R. W. Lloyd exhibited a specimen of *Carabus catenulatus*, in which the femur of the right foreleg was curiously dilated and toothed.—The Rev. C. F. Thornewill exhibited a black variety of the male of *Argynnis aglaia*, taken by himself in July last on Cannock Chase; also a number of living larvæ of a species of *Eupithecia* feeding on the flower-heads of *Tanacetum vulgare*. He expressed some doubt as to the identity of the species, but the general opinion was that the larvæ were those of *Eupithecia absynthiata*.—Mr. H. Goss exhibited, for Mr. G. Bryant, a variety of the larva of *Trichiura cratægi*.—Mr. C. G. Barrett exhibited a specimen of *Plusia moneta*, Fabr., a species new to Britain, taken at Reading in July last. Mr. Goss stated that the first specimen of this species had been taken at Dover last June, and was now in the collection of Mr. Sydney Webb, of that town. Mr. Kirby said that Mynheer Snellen had reported this species as being unusually common in Holland a few years ago.—Mr. W. Dannatt exhibited a variety of *Papilio hectorides* from Paraguay. Mr. O. Salvin, F.R.S., said he had seen this form before.—Mr. C. J. Gahan exhibited a curious little larva-like creature, found in a mountain stream in Ceylon, and observed that there was some doubt as to its true position in the animal kingdom. It was made up of six distinct segments, each of which bore a single pair of laterally directed processes or unjointed appendages. Mr. Hampson remarked that the appendages were very suggestive of the parapodia of certain chætopod worms. Lord Walsingham and Mr. McLachlan expressed an opinion that the animal was of myriopodous affinities, and was not the larva of an insect.—Mr. Baker read a paper entitled "Notes on the genitalia of a gynandromorphous *Eronia hippia*."

PARIS.

Academy of Sciences, October 6.—M. Duchartre in the chair.—On the determination of integrals of certain equations from partial derivatives of the second order, by M. Émile Picard.—On the balls of fire or electric globes of the St. Claude tornado, according to the report of M. Cadenat, by M. H. Faye. Prof. Cadenat, of the St. Claude College, has brought forward a number of testimonies as to the appearance of many balls of fire during the storm of August 19. It is a remarkable fact that the United States tornadoes are rarely accompanied by globular lightning discharges like those observed during the recent storms of Dreux or St. Claude. The cause may be that American tornadoes have been most frequently observed in broad daylight, whilst in France those of August 18 and 19 appeared towards the evening.—On the movement of Foucault's pendulum, by M. de Sparre. The author establishes the complete formulæ for the movement of Foucault's pendulum in air, and shows that the resistance of the air has an indirect influence on the velocity of rotation of the plane of oscillation, both diminishing the amplitude of the vibrations, and causing deformations in the curve described.—Some theorems on similar plane figures, by M. P. H. Schoute.—On a new method for testing urea, by M. M. P. Miquel.—Destruction of the tubercular virus by the products of the evaporation of certain substances, such as a mixture of alcohol and different essences, on spongy platinum, by M. Onimus.—On the fecundation of *Hydatina senta*, Ehr., by M. Maupas.—Experiments on the cultivation of wheat in a sterile siliceous soil, by M. Pagnoul. The experiments show that phosphates, especially in the soluble form, play an important *rôle* in the production of wheat; in fact, the suppression of phosphoric acid retarded the maturity of plants about ten days. The richness of the grain in nitrogenous matters increases with the proportion of nitrogen at the disposal of the plant. It it is found to decrease to 8 or 9 per cent in plants grown in soil containing no nitrogen, and reaches as much as 20 per cent—that is, much above the average—in those grown in soils in which the assimilated nitrogen was greater than that of the most fertile soils.—Observations of the part played by fluor in mineralogical syntheses, by M. Stanislas Meunier. The author finds that the introduction of fluorides renders the synthesis of labrador, nephelite, and leucite remarkably easy and rapid, and does away with the necessity for very high temperatures.

BRITISH FARM, FOREST, ORCHARD, AND GARDEN PESTS.

British Farm, Forest, Orchard, and Garden Pests. A Manual of Injurious Insects, with Methods of Prevention and Remedy for their Attacks to Food Crops, Forest Trees, and Fruit, to which is appended a Short Introduction to Entomology. Compiled by Eleanor E. Ormerod, F.R.Met.Soc., &c. Second Edition. (London: Simpkin, Marshall, Hamilton, Kent, & Co., 1890.)

THE first edition of "The Manual of Injurious Insects" was published in 1881, and was then justly considered by all entomologists to be the most important work upon economic entomology since Kirby and Spence wrote their famous "Introduction to Entomology," "combining," as John Curtis said, "truth, instruction, and amusement." It was undoubtedly also by far the most exhaustive account of insects destructive to agricultural and horticultural crops that had been produced since the appearance of the admirable "Farm Insects" of Curtis in 1860. The second edition of this useful "Manual of Injurious Insects" has been recently issued, and contains in addition to the vast stores of information concerning all manner of insects which attack farm and garden crops, the results of the devoted labours, keen research, and scientific observation of Miss Ormerod, during a period of nine years.

In point of volume and matter this last edition is nearly twice as large as the first. As regards interest, practical value, and science, it is likewise of much more importance, because it records the discovery of insects altogether new and undescribed in this country, as well as measures of prevention and remedial methods against these and many other insects, that have been prescribed and adopted within the past decade. It describes, in short, the advance which has been made in economic entomology in this period, in the knowledge of insects, of their life histories, and habits, and of means to protect the crops of cultivators against their ravages. And no one is better qualified to relate this progress than Miss Ormerod, who has herself contributed so greatly towards it.

Most of this new matter has been previously given for the edification of the public and the advantage of farmers in Miss Ormerod's "Annual Reports of Observations of Injurious Insects and Common Farm Pests." It is condensed in the new manual, and arranged under different headings, or parts. These are three, the same as in the first edition. Part I.—Food crops and insects that injure them. Part II.—Forest trees and insects that injure them. Part III.—Fruit crops and insects that injure them.

An Introduction to Entomology is given in this edition as an Appendix, while in the former it precedes the three parts, or divisions. It may be said of this, in passing, that it will be most useful to students of entomology, as it gives in concise terms the main points by which insects of various orders and species may be distinguished in each stage of their life histories. The classification of insects is plainly set forth so that beginners may see almost at a glance the primary division of insects into the two great tribes, *Mandibulata* and *Haustellata*, and the subdivision of the one into eight orders, and of the other into five orders, in accordance with the rational arrangement of Prof. Westwood.

Among the troublesome insects treated of in Part I. are several species of butterflies, moths, and flies which attack cabbages, as the large and small white cabbage butterfly, *Pieris brassicæ* and *Pieris rapæ*, the cabbage moth *Mamestra brassicæ*, the cabbage fly *Anthomyia brassicæ*, and others more or less injurious to the brassica tribe. Complete histories are furnished of all these insects, and valuable means of prevention are advised and remedies suggested of a practical nature that can easily be adopted, both on a large scale suitable for farmers and market gardeners, as well as for gardeners and allotment holders.

There is an important monograph of the carrot-fly, *Psila rosæ*, which will be gratefully received by market gardeners and market garden farmers, as the fly has in the last few years been especially destructive, not only in England, but also in Scotland and Ireland. This attack is generally termed "rust," because the leaves of the carrots become yellowish, or rusty coloured, and the roots are covered with rusty patches. To one unacquainted with entomology and not having good eyesight, it is difficult to trace the cause of the disorder to the tiny maggots of this fly in the roots of the plants. Upon very careful examination, however, a diseased carrot will be found to be swarming with legless, slimy, yellowish maggots, not a quarter of an inch in length, many of which are found to be sticking half in and half out of the roots. Miss Ormerod says:—"The grubs may be found in winter as well as summer, and attack all parts of the carrot-root by gnawing galleries on the surface, or into the substance of the root; but whilst the roots are young, the grub appears generally to attack the lowest part." This is not always the case, for in some young carrots examined in July last, which were sent from Ireland, the crowns of the roots were as full of the maggots as the ends.

Under the head of prevention and remedies for this affection, it is stated—

> "The following notes regarding carrot cultivation will be found to bear in various ways suitable to different circumstances of soil and climate on the main points of —1st, such preparation of the ground in autumn, or winter, as will ensure favourable conditions for a healthy, vigorous, and uninterrupted growth from the first sprouting of the seed; 2nd, thinning at such a stage of growth, in such circumstances of damp weather or with such watering or treatment after thinning as may least expose the plants to the attack of the carrot-fly which frequently occurs after this operation. Whether the fly is attracted by the scent of the bruised plants, or what brings it, is not clear, but it is very clear that, as it goes down into the ground to lay its eggs on or by the carrots, all operations which leave the soil unusually loose and open lay at the same time the carrot roots open to attack, and it will be observed that the various methods of treatment in regard to thinning bear upon the means of meeting this difficulty."

This is given as one instance of Miss Ormerod's powers of observation as to the habits of insects, which enable her to recommend suitable and effective remedies and methods against them. The practical conclusion in this

case is that carrot-growers should thin carrot-plants early, and draw the soil as close as possible, and make the soil very firm around them immediately after thinning has taken place.

Again, "although the summer broods hatch in three or four weeks the maggots may be found in the roots during the winter, and they change to pupæ in the earth adjacent. It is therefore very desirable that all infested carrot-beds should be thoroughly cleared of roots in the autumn, and the ground well dug, or trenched, so that such maggots or pupæ as remain in the bed may be destroyed; some may escape, but the larger number will thus be buried too deeply to come up again or be thrown on the surface to the birds; and a dressing of gas-lime will be serviceable in destroying such of the maggots as are lying near the surface."

Remedies are prescribed for this attack in the shape of dressings with spirits of tar mixed with sand, and of paraffin oil and sand; also waterings with dilute soluble phenyl and paraffin oil, in the proportion of a pint of paraffin to two gallons of water.

Among the many insects that injure corn crops whose histories appear in this "Manual," is a group of flies, among which are the frit fly (*Oscinis frit*)—a minute fly, not the eighth of an inch long, whose attention seems to be confined to oats. The maggot coming from the egg laid by this "fly feeds in the heart of the young oat-plant a little above the ground-level and eats away the centre, so that the shoot above the eaten part is destroyed, and the damage that is going forward then becomes noticeable from the injured shoots turning brown and withering instead of continuing their growth."

The frit fly has been well known in France, Germany, and particularly in Sweden, where it attacks barley, but until 1888, when the attacks of the frit fly were very prevalent in Devon and Cornwall, not much was known of it in this country, although, as Miss Ormerod points out, "the presence of the *Oscinis vastator*, Curtis, which appears to be the same as *Oscinis frit*, was watched and recorded in 1844 by John Curtis in his 'Farm Insects.' In 1881 I was favoured by Mr. R. H. Meade, of Bradford, with the information that the *Oscinis frit* had been observed in the autumn of that year in swarms in an outbuilding, in the lofts of which a lot of newly-threshed barley had been stored, which points to the Swedish form being then present; but it was not until 1887 that I was able to watch this attack throughout its course, up to the development of this fly as a regular field attack."

Farmers now find another fly, the "gout" fly, or ribbon-footed fly, *Chlorops tæniopus*, to be a frequent enemy to wheat, rye, and barley plants. This, as shown in the "Manual," is most prevalent on barley, and is mentioned by Curtis as having done much harm, in 1841, in Surrey and Lancashire. Now it is found in most parts of the country, and is a striking instance of the general spread of insect pests within the last few years among cultivated crops of all kinds.

The action of this insect is thus described by Miss Ormerod:—"Whilst the plant is still young and the forming ear is wrapped in the sheathing leaves, the fly places her eggs either within these leaves or so that the maggot can make its way through them to the ear; there it usually eats away some parts of the lower portions of the ear, and then gnaws or, rather, tears a channel down one side of the stem to the uppermost knot, and beneath the leaves the maggot changes to a reddish chrysalis, from which the gout fly appears about harvest time."

It has been a moot point where this insect passed the winter in this country. In Germany, as Taschenberg states in his Praktische Insekten Kunde, the flies place their eggs on grasses and autumn sown corn, upon which hibernation takes place either in larval or pupal form. As reported by the Consulting Entomologist of the Royal Agricultural Society of England, pupæ of the chlorops were discovered in the main stems of wheat plants just above the ground, in England, in the early part of the spring of 1890 by Mr. Whitehead. The time when these were found and the evident injury caused to the plants proved that the insect had hibernated within their stems.

Another insect belonging to the group of corn flies is the corn saw fly, *Cephus pygmæus*, a very small insect which pierces the stem of wheat and barley plants "just below, or at one of the knots, and inserts there an egg, continuing this process successively to other stems until her egg supply is exhausted. The maggot, which hatches in about ten days, is about half an inch long, yellowish white, fleshy, with a horny, rusty-coloured head, and is peculiar in being footless, although the larva of a saw fly. It feeds on the inner substances, clearing its way sometimes through the knots, even through the topmost, and when nearly full-grown comes down inside the stalk on which it has fed; and about harvest time, or a little before, it comes down to the ground level, where it gnaws a ring so neatly and cleanly round inside the stem that the straw readily falls with its own weight, or from a slight pressure of the wind, the severed stalk showing almost as smooth a fracture as if it had been separated by a knife. When the maggot has thus travelled down the stalk and nearly cut it through (so that nothing may prevent its escape presently as a fly) it goes down into the lowest part and spins itself a silken case in which it passes the winter."

The wheat-bulb fly (*Hylemia coarctata*), though only identified in 1882, has now become one of the pests to be dreaded by wheat growers. Curtis does not speak of it, and it was first distinguished in this country by Miss Ormerod. Taschenberg speaks of this fly as destructive in parts of Germany, and says there are two broods there. As this seems to be a new destroyer here, it is possible that it was brought from Germany with imported straw or produce of some kind.

In the "Manual" it is observed that the attacks of the maggots of the wheat-bulb fly and those of the frit fly are much alike, so far as the method of injury is concerned. But here Miss Ormerod's entomological knowledge and acute perception of the smallest distinctions serve to show how the different flies may be recognized. In the maggot or larva of the wheat-bulb fly "the tail segment projects, and ends in two squarish-ended teeth with flattened edges placed centrally, with one pointed tooth, and sometimes more, on the central square part. . . . The presence of these teeth and the *absence of* a little bunch of stalked spiracles near the head appear to me to be the simplest way of knowing the wheat-bulb from the frit maggots."

The Hessian fly, another member of the group of stem

flies, having first appeared in Great Britain in 1886, is graphically described by Miss Ormerod, who has done so much to familiarize agriculturists with the dreaded scourge, and to make them acquainted with preventive measures and remedies against it. This information, published from time to time, is concisely summarized, so that it may be said that, in the few pages devoted to this insect, all that is known about it is plainly set forth.

The least generally known facts connected with the Hessian fly, and those of the most scientific interest, relate to its parasites, which have been carefully studied by the authoress, who had the advantage of long consultations with Prof. Riley in 1887.

The importance of the various parasites of the Hessian fly in tending to keep it down in this country is great. By some it is believed to be desirable to rear them and take them to places that are badly infested, just as, recently, parasites were imported from Australia to destroy the *Icerya purchasi* in the Californian orange groves. It is certain that in this last summer the attack of the Hessian fly was immensely modified by the parasites, which were present in unusual numbers. In several instances where the pupæ of the Hessian fly were transferred to live cages, at least 70 per cent. proved to be parasitized by at least three different kinds of flies. Miss Ormerod and Prof. Riley agree that the parasites of the Hessian fly in Great Britain are of the same species as those found in Russia, and differ from those which infest the Hessian fly in America. Comparative lists of the American and Russian Pteromali are submitted, from which it is seen that they are of the same genus, but not of identical species. "The examination of our parasites," Miss Ormerod concludes, "pointed, therefore, very strongly to the probability of our Hessian fly attack having been imported to us from the east of Europe." And, further, it is suggested that it originated, not in straw imports, as it was first imagined, but in the pupa, or "flax-seed," condition in foul grain imports.

In Part II., devoted to the insects that injure forest-trees, among the principal offenders is shown to be the elm-bark beetle, *Scolytus destructor*, which makes the well known galleries between the bark and the wood, "mainly in the soft inner bark, but so as to leave a slight trace of the working on the surface of the tree." This beetle often causes serious injury to elms both in this country and on the Continent. It generally attacks trees, or the parts of trees that are inclined to disorder, or decay, or that have been previously attacked by beetles. To circumvent the operations of this insect, Miss Ormerod recommends that the rough bark should be scraped off, so that the larvæ are exposed to air, or driven out by the flow of sap from the inner lining of the bark. This was found to answer in France, where upwards of 2,000 trees were thus treated.

The ash-bark beetle, *Hylesinus fraxini*, injures ash trees in the same manner by making galleries beneath the bark, particularly in young trees. It is advised that the bark should be treated with a good coat of soft soap well rubbed into the affected parts of the trees.

Yet another boring beetle is given, known as *Hylurgus piniperda*, or pine beetle, injurious more on account of the harm the beetles cause by boring through the side of the tender shoots of young pine trees and eating their way for an inch or more along the pith, than from the galleries made by the larvæ in pine timber. As they often select dead or diseased trees for boring into for breeding purposes, felled trees should be at once removed and diseased branches or limbs of trees in infected woods should be cut off and carried away. Or traps may be set for the beetle by placing "young Scots pine tops, thinning off all the branches (which makes them convenient to handle) in the plantations or against the lower part of the standing trees." The beetles select these for laying their eggs upon, and they should be taken away and burned in June.

Another pine beetle, *Hylobius abietis*, is even more injurious to many of the coniferæ than the *Hylurgus*. It may be entrapped in the same manner, as it frequents forest clearings, that is, where fir trees, few or many, have recently been felled, and lays its eggs also on logs and stumps.

Against the attacks of many other insects troublesome to trees, such as the pine-bud moth, the pine-shoot moth, the pine saw fly, the spruce gall aphis, the larch aphis, the willow beetle, and the oak-tree roller moth, methods of prevention and remedies are prescribed. This part of the "Manual" cannot fail to be most instructive and useful to those in charge of woods and forests.

In Part III., treating of fruit-crops and insects that injure them, twenty-three different insects are fully described, and in all cases practical suggestions are made for preventing their onslaughts upon the fruit crops, and for diminishing the virulence of their attacks. These suggestions are most timely, as during the last few years the fruit crops of almost all descriptions have suffered much from insects. Not only have new kinds of insects arisen, but long-known foes have increased and multiplied to a terribly dangerous extent, so that whole districts have been cleared of fruit. For example, in the spring of each of the last three years hosts of caterpillars of several species have ruined the apple, plum, and damson crops in many parts of Kent, and in other fruit-producing counties.

Among the fruit pests that have recently sprung up are the white woolly scale, *Pulvinaria ribesii*, found last year upon currant bushes to a considerable extent. A figure of a currant twig covered with white cottony, or woolly matter, forming a covering for the eggs and young scales is appended, which conveys a good idea of the "almost overwhelming nature of the infestation and the serious amount of injury caused by it." This attack has been known in France for some time, and is mentioned by Signoret in his "Essai sur les Cochenilles." Miss Ormerod recommends applying limewash to the infested bushes with a brush, "the same process as whitewashing." Where remedies cannot be brought to bear, or fail, "it would be best to cut off and burn the infested branches, or to destroy and burn the infested bushes if it could be done without serious loss, and thus stamp out this newly-observed pest in time."

A fruit-tree boring beetle new in this country, but well known in Germany and America, from whence it was probably imported, was identified by Miss Ormerod in 1889 as the "Shot-borer," *Xyleborus dispar*. This was found in Lord Sudeley's fruit plantations in Gloucestershire, in the stem of a young plum tree into which it had

bored and killed the tree. Several trees were killed in the same manner. The great peculiarity in these insects is the disparity in size between the females and males, from which it is termed *dispar*. The female is about the eighth of an inch long, while the male is only about two-thirds of this length. The injury begins by a small hole like a shot-hole being bored in the side of the stem, from which a tunnel is made into the pith, and a branch tunnel running horizontally about half, or two-thirds, round the stem. Other tunnels are made straight up and down. These borings, and the destruction of the pith, soon serve to kill the branch. The only remedy appears to be to cut off and burn the infested limb, and "coating the trees with some wash or mixture, which will not hurt the bark but will prevent the beetle getting in or getting out. One application advised for trial is a thick coat of whitewash with some Paris green in it."

There is a detailed account of the winter moth, that arch enemy of apple, pear, and plum growers; this is particularly valuable, as it gives the latest experience of practical growers with respect to preventive and remedial measures. The most important of these is the careful banding of the trees in the autumn, before October, with grease and offensive compounds, to prevent the females from climbing up, and the use of arsenites (Paris green and London purple) for washing or syringing infested trees. These washes have been proved to be efficacious in America, where they are universally applied for many insect attacks. In this country, however, cultivators have hesitated to use them on account of their poisonous nature. Miss Ormerod plainly shows that they may be employed without danger and with vast benefit to the fruit grower. For plum trees, the proportion is 1 ounce of Paris green to 10 gallons of water, and for apple trees 1 ounce to 20 gallons. Testimony is given from various growers as to the efficacy of this wash, which from henceforth will, it is presumed, be adopted, as it seems to be the only one which will check the ravages of moths injurious to fruit trees. Full details concerning the use of these American remedies for insect attack are given, which must be most serviceable.

Want of space prevents allusion to many other insects described in this part of the work. It can only be said that they are clearly and minutely defined, and all that is known of their habits and of means to avert or to modify their mischief is set forth.

The "Manual" is replete with capital figures of the insects in all stages. Many of these are from drawings executed by Miss Ormerod, and many are the well-known accurate and inimitable designs of Curtis.

TORNADOES.

The Tornado. By H. A. Hazen, Assistant Professor of the United States Signal Office. (New York: Hodges, 1890.)

THIS is a book that will hardly enhance the reputation of its author. Despite his assurance (which of course will not be questioned) that he has endeavoured throughout to be absolutely unprejudiced, its apparent aim is not so much to set before the reader a concise description of tornado phenomena as to controvert the views put forward by Ferrel and others relative to their mechanical and physical constitution, and to substitute for these certain other speculations (we can scarcely call them a theory) which appear to the author to have the merit of greater probability. Prof. Hazen does not, indeed, restrict his condemnation to Ferrel's theory of tornadoes and thunder-storms. As a root-and-branch reformer, he finds himself in opposition to the majority of those who, during the last quarter of a century, have built up the fabric of modern meteorology, for, while he speaks with deference of "the epoch-making experiments of Mayer [*sic*] and Joule," he appears to regard as inapplicable to the movements of the atmosphere those laws of thermodynamics which are based on the results of Joule's labours. Were it the practice of scientific authors, in imitation of romance-writers, to head their chapters with quotations appropriate to the subject-matter, chapter v. of this treatise, more especially, might be fitly introduced with the well-known lines from "Faust":—

> "Ich bin der Geist, der stets verneint!
> Und das mit Recht! denn alles was entsteht
> Ist werth, dass es zu Grunde geht";

substituting, however, "*entstanden*" for the present tense of the verb.

Lest it should be thought that these remarks misrepresent or exaggerate the sweeping character of Prof. Hazen's "objections," we extract one or two passages from the chapter in question. On the generally-accepted view that work is performed by an ascending current of air, in pushing aside the atmosphere into which it expands, and that in saturated air the requisite energy is furnished, in part at least, by the condensation of vapour, he observes (p. 52),

"There is nothing in the science of meteorology, or possibly in any physical science, that has been developed from such a worthless origin as this theory of the liberation of energy on the condensation of moisture";

again (p. 54),

"All the reasoning regarding the diminution of temperature in dry and moist air, as we ascend in the atmosphere, is founded upon purely theoretical considerations. Every experiment, whether in the laboratory or in Nature, has proved that these theories, in their sum and substance, are false";

and again (p. 56),

"I am inclined to think that even Espy, with all his disadvantages, was too well informed to adopt such a doubtful and visionary idea as this of effective work performed in the free upper air."

The familiar lecture experiment illustrative of dynamic cooling, in which a cloud is produced in a receiver containing moist air by partially exhausting it with a few strokes of the air-pump, is interpreted in a novel manner consistently with the above opinions (p. 67):—

"The presence of haze or cloud is no evidence of saturated air, for such cloud has been produced in air having only 2 per cent. of moisture.[1] When air is pumped from the room, it has an enormous number of dust particles in it, and these give the appearance of a fog on sudden expansion."

After these samples of the author's opinions it will be scarcely necessary to notice, in detail, the other numerous

[1] Prof. Hazen does not give his authority for this statement, nor does he specify whether the expression is to be understood as 2 per cent. of saturation, or 2 per cent. by weight or volume. If the former, authentication seems desirable; if the latter, the fact is obviously irrelevant.

points on which Prof. Hazen's views are in dissonance with those of most other writers who have treated of tornadoes. Among others, he assures us (p. 57), that "the evidence for [their] gyrations is exceedingly contradictory, and the weight of evidence is overwhelmingly against them"; that (p. 52) it is impossible that warm south wind underruns that which is cooler from the north, "for the denser must always be beneath the lighter"; and (p. 59) that it seems impossible to ascribe the progressive movement of the tornado to the drift of the upper current, "because it moves with a velocity double that of the general storm." Those who are curious to see the further arguments by which these theses are supported must be referred to the work itself. We have yet to notice briefly the alternative views advocated by the author.

The late Dr. Percy used to relate that, in his early days, when the iron would not "come to nature" in the Staffordshire puddling furnaces, the workmen were accustomed to ascribe its perversity to the presence of sulphur in the charge. In still more remote times, the potentate in whose realm that element is supposed to be somewhat abundant, or his agents, would assuredly have been held responsible for what was amiss. But thirty years ago the march of science had brought in other ideas, and the approved explanation of any otherwise unaccountable difficulty of the kind was that electricity had something to do with it. Even at the present day this mysterious agency is the favourite resource of puzzled tyros in physical reasoning, but we should hardly have expected to find it seriously put forward in all its familiar vagueness by an author whose official designation is that quoted above from the title-page of his work. That such, however, is the case stands in evidence in the following extracts, which we give as fully as our space will admit of, lest we should fail to do their author justice:—

"It is very difficult to believe that electricity has nothing to do with our thunder-storms, and is merely a result and never a cause. . . . Our thunder-storms seem to show an enormous storehouse of electricity at five thousand or six thousand feet above the earth; at least electricity seems to be concentrated there over thousands of square miles during thunder-storm action. We are taught that electricity forms a sort of dual condition, or the electric field is a double one.. May not this electric field draw on the sun for its energy? . . . Why may not the sun's electricity, oftentimes observed by its direct effect on our magnetic instruments, and, more often still, indirectly in our auroras, be intercepted by a peculiar condition of the atmosphere or of the earth below, and thus be concentrated in particular localities?"

This may, perhaps, appear somewhat vague as an alternative theory of storm generation; in one particular, however, viz. the accumulation in the storm-cloud of the enormous quantities of water precipitated in cloudbursts, the *modus operandi* is more fully explained. In Prof. Hazen's opinion, it would seem that electricity performs a part in the atmosphere somewhat analogous to that of Clerk Maxwell's hypothetical demons, and which is described as follows:—

"Is it inconceivable that we have to deal here with a negative electric field, which draws to itself with great velocity particles of moisture from regions perhaps for one hundred miles about, when suddenly, upon a discharge of electricity, the potential upon the particles is diminished, and they unite in great abundance and form rain-drops?"

This remarkable speculation, it is considered, receives support from a novel experiment described as follows:—

"A Holz machine was run for fifteen minutes in a rather large room; and most careful measurements of the amount of moisture at the machine and at a point twenty feet away, before and after the machine was in action, showed an increase at the machine. When we consider that it was impossible to measure the moisture contents just at the plate of the machine, and also what an extremely slight charge could by any possibility enter the air from the machine, we can but be surprised that any effect at all was observed."

Without imitating King Charles the Second's scepticism in the matter of the fish's weight in water and out of water, but accepting Prof. Hazen's statement of the results as he gives them, we may still inquire whether the operators who worked the Holz machine continuously for fifteen minutes did not exhale a considerable quantity of water vapour in the neighbourhood of the machine. Perhaps they even perspired freely with their exertion. In any case the foundation seems hardly adequate for the superstructure.

Had this book appeared under a less known name, and were it not for the official position of the writer, we should scarcely have deemed it desirable to notice it at such length. A really searching, intelligent criticism of Ferrel's theory, by one who has exceptional advantages for ascertaining the facts of observation, would have been welcome; for, symmetrical as that theory is, it is still mainly deductive, and there are many points in it, and these not the least important, which still lack confirmation. But we cannot attach much weight to the objections raised by Prof. Hazen. They seem to betray a strange misconception of the physical processes which he condemns in such uncompromising terms; and where his arguments turn on the facts of observation, we must decline to accept his sweeping denials, in the face of the positive testimony of numerous, not incompetent, observers. In some cases, indeed, we might adduce our own personal experience of phenomena which are declared by him to be improbable or impossible. Such are, for instance, the superposition of dry northerly above warm and moist southerly currents, and the spiral movement of the air in dust whirls, which, on a miniature scale, represent that of the tornado.

Again, Prof. Hazen's argument that the rise of pressure beneath a thunder-storm is sometimes observed in storms that are rainless, and therefore cannot be due to the cooling of the air by the rain, or to its downward pressure as it falls, is rendered of little weight by the fact that this occurs only when the lowest strata of the atmosphere are very dry. In the recently published "Climates and Weather of India," it is stated that "a complete transition may be traced between [the rainless dust-storms of Upper India] and the north-westers of Bengal, which are accompanied by heavy rain." In the latter province "the dust-storm is. as a general rule, only the first stage of a north-wester." It is attended with a sudden rise of pressure, and "is followed by heavy rain and sometimes hail," and though the dust-storms of the former are occasionally, though perhaps rarely, quite rainless,

"the coolness of the wind and that of the atmosphere after the storm is over is hardly to be accounted for otherwise than by supposing that rain is always formed in the cloud overhead, but is re-evaporated before it reaches the earth."

There is nothing inconsistent in the existence of an excessive pressure at the ground surface beneath a thunder-storm and a diminished pressure in the vortex of the storm-cloud, but in ordinary thunder and hail storms this latter is restricted to the cloud-region. As the barograph traces of these storms show, the oscillations of pressure beneath them are very great, and there may and indeed must be still greater differences between the tornado vortex and the neighbouring region of precipitation. Indeed, the great velocity of the air-movement implies as much.

A part of Ferrel's theory which especially stands in need of confirmation is the assumption that, immediately prior to the formation of the vortex, the vertical distribution of temperature is such as to bring the atmosphere into a state of unstable equilibrium, and that a slight casual local disturbance of this equilibrium starts the vortical uprush. This is also his explanation of cyclone generation, and indeed it is that hitherto held by the majority of writers on the subject. On the other hand, it is generally considered that anticyclones are determined by the greater local density of the atmosphere, due to a low mean temperature of the air-column. The last of these assumptions, even in the case of winter anticyclones accompanied by very low temperatures at the ground surface, has now been conclusively disproved by Prof. Hann, of Vienna; and he has also shown very strong reasons for believing that the temperature conditions of extra-tropical cyclones are also incompatible with the prevailing view. It does not, of course, follow that those of tornadoes and hail-storms are equally so, but at least the assumed conditions require verification. This may, perhaps, be some day effected by our mountain observatories.

OUR BOOK SHELF.

Inorganic Chemistry: the Chemistry of the Non-Metals. By J. Oakley Beuttler, M.A. (London: Relfe Brothers.)

NOW that there can be obtained a considerable variety of really good text-books of elementary chemistry suitable for all the usual needs of the present day, one is entitled to look for special features in any new manual. We fail to find any reason for the existence of the volume before us: wherein it differs from others that enjoy general recognition, it is incomplete and erroneous. It has neither index nor contents table, but this is quite a trivial matter when compared with the imperfections of the body of the work. On pp. 19 and 20 there are nine attempts at equations, none of which are correct, while many represent impossible or at least unknown reactions; and in the following paragraphs, on graphic notation, bonds, and radicles, there is a collection of statements that read like the imperfect recollections of a student who never understood the subject. A single atom of oxygen is shown with curiously shaped projections as an example of an element with an even number of bonds existing as a single "atom-molecule." It is stated emphatically that "the element having the greatest number of bonds is always printed in thick type," but we search in vain for thick type in any formula in the book. The statements that are intended to convey the facts of chemistry are vague, often misleading, and very rarely of a practical character. For an illustration of the style there is no need to go further than the chapter that treats of the first element, hydrogen. It states that "on throwing a piece of sodium into water the sodium combines with part of the hydrogen of the water to form caustic soda, liberating the other part of the hydrogen." The volume closes, as one would expect, with the questions set by various examining bodies during the last three or four years.

Anatomy, Descriptive and Surgical. By Henry Gray, F.R.S. Twelfth Edition. Edited by T. Pickering Pick. (London: Longmans, Green, and Co., 1890).

OF a solid text-book so well known as the present work it is hardly necessary to say more than that a new edition has appeared. The book has been carefully revised, and the editor has added considerably to its value by introducing sections on topographical anatomy, and amplifying those on surgical anatomy. Both of these classes of sections have been printed in smaller type, so that they may be disregarded by students who wish to confine their attention exclusively to the descriptive part of the subject. There are many new illustrations, some of which are original.

The Story of the Heavens. By Sir Robert Stawell Ball, LL.D. Fifteenth Thousand. (London: Cassell and Co., 1890.)

IT is, for many reasons, satisfactory that there should be a popular demand for a clear, brightly-written work on astronomy. Sir Robert Ball, however, ought hardly to be content with the issue of mere reprints of his book. It may be somewhat misleading to send forth in its original form, in 1890, an astronomical work first published in 1886.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Passage of Electricity through Gases.

IN my letter in NATURE of July 24 (p. 295) I objected to Prof. Schuster's statement that the fact that free atoms must turn a gas into a conductor of electricity was fatal to the theory of the electric discharge given by me in the *Philosophical Magazine* in 1883, and I maintained that the presence of free atoms in a gas free from electric strain was in no way essential to the theory given in that paper. I see no reason, after reading Prof. Schuster's letter in this week's NATURE, to change that opinion. Prof. Schuster bases his statement, not on my description of the theory itself, but on the explanation by it of the weakening of the electric strength produced by a diminution in the density of the gas. A reference to this explanation will show, however, that it really rests solely on the well-known fact that dissociation is assisted by diminution of pressure, and that the passage which Prof. Schuster quotes is merely an explanation of this property of dissociation from the point of view of the kinetic theory of gases; if this explanation is held to be inconsistent with the absence of free atoms from gas in a normal state, then any alteration in the explanation which might be made to meet this difficulty, though of primary importance in the kinetic theory of gases, is only of secondary importance for the theory of the electric discharge given in my paper, which I still maintain is not all bound up with the existence or non-existence of free atoms in gases not in the electric field.

J. J. THOMSON.

Cambridge, October 18.

Changing the Apparent Direction of Rotation.

IN NATURE of October 16 (p. 585), a curious optical effect is incidentally mentioned. Standing near a windmill, and nearly

in the plane of the sails, "it is possible, by a slight mental effort, to change the apparent direction of rotation, and back again."

A similar effect I have often observed, but it seems in no way dependent on the will. Look, for say 30 seconds, steadily at the revolving disks of an anemometer; they will soon reverse their apparent direction, whether you wish it or not. Continue still to gaze, and that reversed direction will be changed back.

All whom I have asked to try this experiment felt the effect to be involuntary. The changes take place not gradually or confusedly, but distinctly and with decision. The fact is plain; the explanation not so simple. HERCULES MACDONNELL.

4 Roby Place, Kingstown.

Earthquake Tremors.

PERMIT me to say that Mr. John Perry, in his criticism (October 2, p. 545) of my "Method of observing the Phenomena of Earthquakes," has assumed that the phenomena observed were due to vertical displacement; whereas they were probably due to a swaying of the building in which the observations were made.

This assumption seems also to have been made in the case of the man mentioned by Mr. Wire in your last issue (p. 593).

Marine Villa, Shanklin, I.W., October 18. H. G. DIXON.

A Ball of Fire.

AT about 12.5 last night I was going through the street at Milverton, and saw a bright light about south of me. I saw also a bright ball of fire appear through a break in the clouds proceeding with great rapidity, at about the height of 45°, in a direction which I estimate to be from south to north-north-east; it disappeared behind a church, and I saw nothing more. I am told this may be of interest, and therefore forward the account to you. CHARLES RANDOLPH.

Milverton, Somerset, October 17.

HYDRAZOIC ACID—A NEW GAS.

A NEW gaseous compound of nitrogen and hydrogen has been obtained by Dr. Theodore Curtius, the discoverer of amidogen, and its nature and properties were described by him in the Chemical Section during the recent scientific meetings at Bremen. The composition of the gas is HN_3, and its constitution $\mathrm{H{-}N}\left\langle\begin{matrix}\mathrm{N}\\ \|\\ \mathrm{N}\end{matrix}\right.$. It is, in fact, the hydrogen compound corresponding to the well-known diazobenzene imide of Griess, $\mathrm{C_6H_5N}\left\langle\begin{matrix}\mathrm{N}\\ \|\\ \mathrm{N}\end{matrix}\right.$, the three nitrogen atoms being united in the form of a closed chain. The gas dissolves in water with great avidity, forming a solution which possesses strongly acid properties, and dissolves many metals, such as zinc, copper, and iron, with evolution of hydrogen gas and formation of nitrides, the metal taking the place of the liberated hydrogen. The derivation name of the gas, azoimide, is somewhat unfortunate in view of its strongly acid nature, and Prof. Curtius proposes the name "Stickstoffwasserstoffsäure." Perhaps the nearest English equivalent, open to the least objection, is hydrazoic acid—a name which will serve to recall the many analogies which this acid bears to hydrochloric and the other halogen acids.

In studying the reactions of his recently-discovered hydrazine (amidogen) hydrate, $N_2H_4 . H_2O$, Dr. Curtius found that benzoylglycollic acid, $C_6H_5CO{-}O{-}CH_2COOH$, was decomposed by two molecules of hydrazine hydrate, with elimination of water and formation of benzoylhydrazine, $C_6H_5CO{-}NH{-}NH_2$, and hydrazine acetic acid, $NH_2{-}NH{-}CH_2COOH$, in accordance with the equation

$$C_6H_5CO{-}O{-}CH_2COOH + 2N_2H_4$$
$$C_6H_5CO{-}NH{-}NH_2 + NH_2{-}NH{-}CH_2COOH + H_2O.$$

Under the influence of nitrous acid benzoylhydrazine forms a nitroso compound, $\mathrm{C_6H_5CO{-}N}\left\langle\begin{matrix}\mathrm{NO}\\ \mathrm{NH_2}\end{matrix}\right.$, which spontaneously changes into benzoyl-azo-imide, $\mathrm{C_6H_5CO{-}N}\left\langle\begin{matrix}\mathrm{N}\\ \|\\ \mathrm{N}\end{matrix}\right.$, with elimination of water.

$$C_6H_5CO{-}NH{-}NH_2 + NO{-}OH = \mathrm{C_6H_5CO{-}N}\left\langle\begin{matrix}\mathrm{NO}\\ \mathrm{NH_2}\end{matrix}\right. + H_2O.$$

$$\mathrm{C_6H_5CO{-}N}\left\langle\begin{matrix}\mathrm{NO}\\ \mathrm{NH_2}\end{matrix}\right. = \mathrm{C_6H_5CO{-}N}\left\langle\begin{matrix}\mathrm{N}\\ \|\\ \mathrm{N}\end{matrix}\right. + H_2O.$$

Benzoyl-azo-imide decomposes, upon boiling with alkalies, with formation of benzoate of the alkali and the alkaline salt of the new acid.

$$\mathrm{C_6H_5CO{-}N}\left\langle\begin{matrix}\mathrm{N}\\ \|\\ \mathrm{N}\end{matrix}\right. + 2NaOH$$
$$= C_6H_5COONa + \mathrm{Na{-}N}\left\langle\begin{matrix}\mathrm{N}\\ \|\\ \mathrm{N}\end{matrix}\right. + H_2O.$$

When this sodium nitride is warmed with sulphuric acid, hydrazoic acid, $\mathrm{H{-}N}\left\langle\begin{matrix}\mathrm{N}\\ \|\\ \mathrm{N}\end{matrix}\right.$, is liberated as a gas. The gas is decomposed by hot concentrated oil of vitriol; hence diluted acid requires to be employed, and the gas can thus only be collected in a moist state. HN_3 possesses a fearfully penetrating odour, producing violent catarrh, and dissolves in water with an avidity reminding one of hydrochloric acid. The solution also bears a surprising resemblance to aqueous hydrochloric acid; for, on distillation a concentrated acid first passes over, and afterwards a more dilute acid of constant composition. The aqueous solution possesses the odour of the free gas, and is strongly acid to litmus. With ammonia gas, hydrazoic acid gas forms dense white fumes of the ammonium salt, N_4H_4 or $\mathrm{NH_4{-}N}\left\langle\begin{matrix}\mathrm{N}\\ \|\\ \mathrm{N}\end{matrix}\right.$, a compound which is completely volatile below 100°, and which crystallizes, but not in crystals belonging to the cubic system, in this respect indicating its different constitution to ammonium chloride. The aqueous solution rapidly evolves hydrogen in contact with zinc, copper, iron, and many other metals, even when largely diluted. As in the case of hydrochloric acid, the silver and mercurous salts are insoluble in water, the others being generally readily soluble. As the acid possesses feebly reducing properties, solutions of many of its metallic salts, the copper salt for instance, yield precipitates upon boiling of compounds of the lower oxides of the metals. The barium salt, BaN_6, crystallizes from solution in large brilliant anhydrous crystals. With silver nitrate the aqueous solution of the acid or a soluble salt yields a precipitate closely resembling silver chloride in appearance. Silver nitride, $\mathrm{Ag{-}N}\left\langle\begin{matrix}\mathrm{N}\\ \|\\ \mathrm{N}\end{matrix}\right.$, does not, however, darken when exposed to light, and is further distinguished from silver chloride by its fearfully explosive properties. During the course of his description at Bremen, Prof. Curtius placed a quantity of this salt less than 0·001 gram in weight upon an iron plate, and then touched it with a heated glass rod. A sharp and loud detonation resulted, and the plate was considerably distorted. The mercurous salt, Hg_2N_6, is likewise very explosive. The metallic salts are readily converted into

ethereal salts by reacting upon them with the haloid ethers. The phenyl salt thus prepared, $C_6H_5N\langle{N \atop N}$, is in every way identical with the diazobenzene imide, so long ago prepared by Griess.

A. E. Tutton.

PROF. S. A. HILL.

The last Indian mail of September brings us the sad news of the death of Prof. S. A. Hill, one of the best-known of that small band of scientific workers, to whom we owe our present knowledge of Indian meteorology. He has been struck down suddenly, in the full maturity of his powers, and in the prime of life, after a few days' illness which gave no reason to anticipate so fatal a result. The son of a clergyman in the north of Ireland, Mr. Hill, after studying in the London School of Mines, and taking the degree of Bachelor of Science in the London University, was appointed, in 1876, to the Professorship of Physical Science in the Muir College, Allahabad, and, shortly after his arrival in India, received the additional appointment of Meteorological Reporter to the Government of the North-West Provinces, in succession to Mr. John Eliot, now the head of the Meteorological Department of the Government of India. In these combined offices, Prof. Hill has laboured for nearly fifteen years. In such spare hours as he could dispose of amid the exacting duties of his educational appointment and the administrative work of his office, in a climate which is but little favourable to mental or physical exertion, he devoted himself assiduously to those original investigations which have made his name familiar to the meteorologists of Europe and America. On subjects dealing with questions of terrestrial physics, he published numerous papers of high value and much originality in the Indian Meteorological Memoirs, the Journal of the Asiatic Society of Bengal, the Austrian *Zeitschrift für Meteorologie*, and the *Meteorologische Zeitschrift*; and an elaborate memoir on some anomalies in the winds of Northern India, in the 178th volume of the Philosophical Transactions. In this memoir he boldly endeavoured to map out the distribution of atmospheric pressure over India, at a height of 10,000 feet above sea-level, and showed how this distribution, differing greatly from that at the earth's surface, explains much that is otherwise anomalous in the winds experienced at the lower level, and especially the dry land-winds which play so conspicuous, and occasionally disastrous, a *rôle* in the meteorology of India. To the pages of this journal he was also a not infrequent contributor.

Having regard to Prof. Hill's high powers and his single-minded devotion to the work, of whatever kind, that lay before him, it is somewhat sad to read the following passage in an obituary notice in the Allahabad *Pioneer*, evidently written by one who knew him well. It need hardly be said that the Government referred to is that of the North-West Provinces and Oudh; not that of India, nor of Bengal, the relations of which to their scientific officers are known to be of a very different character. The writer says:—"Many of our readers who will recall their late friend's clear and accurate mind, his knowledge and his powers of application, will feel with a sense of bitterness that men of his capacity are not meant for the service of a Government, which is not only always ready to pass them over for a joint-magistrate who has been unlucky in his promotion, but will maintain that the latter is the best man. Mr. Hill was, officially speaking, the most unfortunate man of an unfortunate service [the educational service of the North-West Provinces]; but, no doubt because he had a talisman always with him in his devotion to science, he was never embittered by his ill-luck. With none of the eccentricities of a disciple of science, but with all the modesty and virtue of that character, he will pass away from us respected by all, and much more than respected by all those who were privileged to know him with intimacy."

H. F. B.

JOHN HANCOCK.

At the venerable age of eighty-four years this well-known British naturalist has passed away, and it would be an injustice to his memory not to recall in these pages the effect of his life-work on the zoology of this country. He seems to have inherited his natural history tastes from his father, who was in business in Newcastle in the early part of the century, but was apparently devoted to natural history pursuits; and, in company with other kindred spirits, was intent on working up the natural history of Newcastle and the immediate neighbourhood. Unfortunately the father died at the early age of forty-three, in September 1812, leaving a widow and six children, of whom the eldest was only eight years of age. Mrs. Hancock, however, carefully preserved the collections which her husband had formed, and it was doubtless due to her affectionate interest that three of her children—Albany, John, and Mary—pursued the study of natural history with such success. The subject of this notice, John Hancock, seems to have turned his attention to ornithology in particular, and as early as 1826 he commenced the study of the artistic mounting of animals, which, as Mr. Bowdler Sharpe has said, has made John Hancock's name a password wherever the art of taxidermy is mentioned. Those who remember the celebrated groups of mounted animals which Mr. Hancock sent to the Great Exhibition of 1851, will testify to the revulsion of feeling which his beautiful work created, and every real naturalist felt in his heart that in this way alone could art and nature be combined in a Museum, and the public properly instructed in a due realization of the beauty and symmetry of form which animals possess in nature—beauties which are not reproduced in a Museum gallery once in a hundred times. That Hancock's influence should have been so little felt by the authorities of the British Museum is a reflection upon the officers of this institution, who ought to have utilized the genius of their countryman in making the collection of British animals in the National Museum a model for all nations to envy and copy. Anyone who knew John Hancock, his untiring energy and his unassuming amiability, will vouch for the fact that, if the British Museum had wished to have a collection of native birds naturally mounted, and worthy of this institution, he would have been only too delighted to aid in the achievement of such a task. As it is, the Museum of his native town, which really seems to have appreciated his genius, possesses a collection of birds of which any nation might be proud, and now that he is gone, those Museums (like the one at Leicester, for instance) which have series of birds mounted by this true lover and *connoisseur* of birds in nature, are to be congratulated. Of late years it is true that our National Museum has trodden the path indicated by Hancock, and a vast improvement in its taxidermy has been the result; but it will be a long time before any Museum can show such a beautiful series of birds as that which John Hancock has mounted for the Museum of his native town. An excellent biography of this esteemed naturalist has been published in the *Newcastle Daily Chronicle* of October 13.

NOTES.

EVERYONE was sorry to hear of the death of Sir Richard Burton, the eminent traveller and Orientalist. He died on Monday morning at Trieste, where he had been British Consul from 1872. He was in his sixty-ninth year. Burton was one of the boldest and most successful travellers of his time, and produced a great impression on all who knew him by the wide range of his talents, and by his energy and manliness. His career as a traveller began in 1852, when he undertook the journey to Medina and Mecca, of which he afterwards wrote so fascinating an account. His journey with Speke in 1857, which led to the discovery of Lake Tanganyika, placed Burton in the front rank of explorers. He had previously made a successful expedition into Somaliland; and at a later period he did much brilliant work in various districts of Western Africa and in Brazil.

WE regret to have to record the death of the Rev. J. A. Galbraith. He died at his residence in Dublin on Monday. For more than half a century he was connected with the University of Dublin, where he graduated in 1840. In 1844 his distinction as a mathematician secured for him a Fellowship, and in 1854 he was chosen Erasmus Smith Professor of Experimental Philosophy, along with Dr. Haughton. Prof. Galbraith was the author of various excellent scientific manuals.

DR. ALEXANDER WILLIAMSON, who died at Shanghai on August 28, had for 35 years been a member of various missionary bodies, and in his earlier years had travelled far and wide over North China, at a time when the greater part of that Empire was unexplored. His "Journeys in North China" is still a work of interest and value, for he visited many districts which are even still far outside the ambits of the missionary and the traveller, and his great knowledge of China renders the work very instructive. But his main work in life was the establishment in Shanghai of the Society for the Diffusion of Christian and General Knowledge amongst the Chinese, which is, we believe, maintained by subscriptions from various missionary societies labouring in China. Up to the time of his death, he was the editor and chief manager of the Society. Under his superintendence some hundreds of cheap books and pamphlets on all branches of science and on literary topics, suitable to Chinese intelligence and Chinese pockets, have been issued by the Society. Usually these were compiled by specialists amongst the missionaries, but occasionally a book already published abroad would be altered to meet the circumstances of the new circle of readers, and published in Chinese. It thus comes about that if an intelligent Chinese, knowing no language but his own, desires to make a closer acquaintance with that Western knowledge and civilization of which he has probably heard so much—whether it be anatomy, zoology, botany, mechanics, steam, the history of Napoleon Bonaparte, the story of the American War, the tale of Robinson Crusoe, the telegraph, the principles of hygiene—he goes to Dr. Williamson's series of publications and selects what he wants, usually at the price of a few cents or halfpence. The Society under his care has in fact stood as an interpreter between the East and West, and has striven to give to the former all the best that the latter has to give in the way of intellectual and moral instruction. This is surely as beneficent a task as can engage the energies of any man, and in it Dr. Williamson appears to have been most successful.

THE Agent-General for the Cape of Good Hope invites applications from gentlemen of appropriate scientific training and experience, willing to proceed to the Colony for a term of years, there to fill one or other of the undermentioned posts under the Government, viz.:—(1) That of bacteriologist, to investigate the diseases of domestic animals, supposed to be caused by germs. The salary offered is £500 a year. A free first-class passage by steamer (including railway fare to port of embarkation) will be provided. (2) That of toxicologist, to attend chiefly to forensic cases and to investigate South African native plants having medicinal properties. The salary offered is £400 a year. A free first-class passage by steamer (including railway fare to port of embarkation) will be provided. Applications must be accompanied by testimonials, and by copies of any scientific publications the applicants may have issued; and should reach the Agent-General for the Cape of Good Hope (112 Victoria Street, London, S.W.) by November 15 next. They will then be submitted to the authorities in the Colony, with whom the appointments rest.

AT the meeting of the organizing committee of the Oriental Congress held on the 9th inst., at the British Museum, it was resolved that Prof. Max Müller should be invited to preside over the Congress. He has accepted the invitation. Sir Henry Rawlinson, who was to have taken the chair, has been compelled to retire on account of ill-health.

THE Council of the Institution of Civil Engineers have issued a list of subjects on which they invite original communications. For approved papers they have power to award premiums, arising out of special funds bequeathed for the purpose. The Council will not make any award unless a communication of adequate merit is received, but will give more than one premium if there are several deserving memoirs on the same subject. In the adjudication of the premiums no distinction will be made between essays received from members of the Institution or strangers, whether natives or foreigners, except in the case of the Miller and the Howard bequests, which are limited by the donors.

THE nomination list of proposed members of the Council of the London Mathematical Society, for the session 1890–91, which will be submitted to members at the annual meeting on November 13 next, contains the following changes:—Prof. Greenhill, F.R.S., to be President, *vice* Mr. J. J. Walker, F.R.S.; Dr. J. Larmor, Major MacMahon, R.A., F.R.S., and J. J. Walker, F.R.S., to be Vice-Presidents. The proposed new members are Dr. Hirst, F.R.S., R. Lachlan, and A. E. Hough Love, in place of Prof. W. Burnside, Prof. Cayley, F.R.S., and Sir James Cockle, F.R.S., who retire. At the same meeting the retiring President will read an address on "The Influence of Applied on the Progress of Pure Mathematics," and will present the De Morgan Memorial Medal to Lord Rayleigh, Sec.R.S., in recognition of his writings on physical subjects.

HERR J. DÖRFLER has successfully completed his botanical expedition to Albania, and has returned to Vienna. From Ueskueb he crossed Kalkandele to Waica, and accomplished the ascent of both the Kobilica and the Serdarica-Duran.

THE late Dr. Henry Muirhead, of Bushyhill and Longdales, Lanarkshire, gave directions in his will that his estate—subject to certain life-rent provisions and legacies—was to be used for the establishment and maintenance of an institution to be named the Muirhead College, "for the instruction and education of women in medical and biological science, where women might receive an education to fit them to become medical practitioners, dentists, electricians, chemists, &c." The trustees, having obtained probate, have had several meetings, and it is expected that in the course of a few months they will be in a position to announce the arrangements they have been able to make. As the estate consists chiefly of lands, its money value must in the meantime be more or less a matter of opinion. The trustees, however, are hopeful that £30,000 at least will be available for the College.

We are glad to hear of the continued progress of what is called the University Hall scheme in Edinburgh. Its objects are (1) to make a beginning of social residence among the students of the University, and (2) to associate with this the extension of University influence among the people. The movement was begun in 1887, chiefly by Prof. Geddes. The house in which the experiment has hitherto been carried on having always had its full complement of residents, another house—an old building of considerable historic interest—has been secured; and this was formally opened the other day by the Solicitor-General for Scotland.

At the eighth meeting of the Congress of Americanists, an interesting address on the peopling of America was given by M. de Quatrefages. He expressed a strong belief in the unity of the human race, and in the consequent facts that the original home of mankind must have been confined to a very limited space, and that the world as a whole has been peopled gradually by processes of migration. He holds that America, like Polynesia, was peopled by colonists from the Old World. The peopling of Polynesia, however, was effected, he thinks, during our Middle Ages, whereas the earliest migrations to America date from geological times.

Under the title of "The Partition of Africa," Mr. Stanford will shortly publish a small volume by Mr. J. Scott Keltie, dealing mainly with the events of the past six years, and their results. In an introductory chapter or two, Mr. Keltie will seek to show what has been the footing of Europe in Africa from the earliest times. He will endeavour to estimate the value of the shares of the various European Powers in the scramble, from the point of view of commerce and colonization.

Messrs. Simpkin, Marshall, and Co., have issued the fifth edition of Mr. Rowland Ward's "Sportsman's Handbook to Practical Collecting, Preserving, and Artistic Setting-up of Trophies and Specimens." In the same volume is included a synoptical guide to the hunting-grounds of the world.

The new number of the *Internationales Archiv für Ethnographie* (Band iii. Heft 4) opens with an interesting paper, by Dr. Ed. Seler, on old Mexican throwing-sticks. Prof. Houtsma contributes notes on some pictures which once served as illustrations of a Persian "Fālbook."

The University College of Wales, Aberystwith, has published the Calendar for its nineteenth session, 1890–91.

The Manchester Literary and Philosophical Society has issued the third volume of the fourth series of its Memoirs and Proceedings. Among the memoirs are the following: on the law of cooling, and its bearing on the theory of the motion of heat in bars, by Charles H. Lees; on the combination of hydrogen and chlorine, alone, and in presence of other gases, by Prof. H. B. Dixon, F.R.S., and J. A. Harker; on some applications of caustic soda or potash and carbon in the qualitative and quantitative analysis of minerals, by Dr. C. A. Burghardt; description of a new reflecting telescope and observatory at Bowdon, Cheshire, by Samuel Okell; on the flexure of a flat elastic spring, by Horace Lamb, F.R.S.; and on absorption spectra and a method for their more accurate determination (with eight plates), by Dr. A. Hodgkinson.

The American Association for the Advancement of Science has issued its Proceedings at the meeting held at Toronto in August 1889.

A brilliant meteor was seen in the northern hemisphere from Edinburgh on Saturday last at 3 a.m. Its advent is said to have been announced by a flash of light which illuminated the whole city. A long fiery streak marked its course, and remained visible for more than a minute.

A report from Honolulu states that an eruption of the volcano Kilauea is feared, as a lava stream has formed lately, and part of it rose 15 metres in one day.

A shock of earthquake was felt at Christiansand, on October 8, at 5.15 a.m. The shock was directed from south to north, and lasted 3 or 4 seconds.

A slight shock of earthquake was felt at Lisbon on the evening of October 17.

According to a telegram sent through Reuter's Agency from Catania on October 18, Mount Etna is in eruption. At the time when the telegram was despatched, a thick column of vapours was rising from the central cone. A slight shock of earthquake had been felt on the eastern side of the mountain at Giarre and its vicinity, where a shower of cinders had also fallen.

Probably the deepest mine in the world (according to *La Nature*) is that at Saint-André du Poirier, in France. Of its two shafts, one 3000 feet, the other 3130 feet, the latter is being sunk to 4000 feet. A remarkable feature of this mine is the comparatively low temperature found in it, never exceeding 24° C. In the gold and silver mines on the Pacific coast, with a depth scarcely half that of French mines, there is great difficulty in keeping a temperature low enough for work. In some parts of the Comstock mines the temperature reaches 48° C.

The Harveian Oration was delivered by Dr. Andrew on Saturday last at the Royal College of Physicians. In the course of the oration Dr. Andrew referred to the fact that the relationship between physiology and medicine has in many ways greatly changed during the last 250 years, and that such change is a necessary consequence of the progress made by physiology. "The goal of physiology is truth—*e.g.* perfectly trustworthy knowledge of a certain class of facts and laws; and this independently of any use, good or bad, to which that knowledge may be put. The goal of medicine is power—*e.g.* ability to manipulate certain given forces in such fashion as to produce certain effects. No doubt, theoretically, the two ends coincide, and we may hope in some remote future they will do so in reality and perfectly. For the present we must be content with having in one direction much knowledge which confers little or no power, and, on another side, very imperfect knowledge which yet brings with it very great power, too often ill-directed. Again, their methods are different. Physiology by slow degrees has come to rely more and more on purely scientific modes and instruments of research, and to apply them by preference to matters which can be brought to the test of direct experiment. Medicine, on the other hand, has no choice but to remain, so far as it has a scientific side, a science of observation; for anything like effective investigation of the matters with which it deals by direct experiment is impossible. As physiology slowly reduces to order the apparently hopeless confusion of so-called vital actions, the easiest questions are attacked and answered first, and thus those which have to be faced later in their turn are more and more difficult, more and more refractory to scientific analysis. Now, these more difficult questions are often of vital importance to medicine, and in them lie dormant vast possibilities of increased knowledge of the nature of disease, of increased power over it. And yet, from the great difficulty of subjecting them to experiment, physiology may seem for a time to fail us, and the task of employing physiological results to explain clinical facts, or to form the basis of rational treatment, becomes harder than ever."

The additions to the Zoological Society's Gardens during the past week include a Speke's Antelope (*Tragelaphus spekii* ♀) from Lake Ngami, South Africa, presented by Mr. James A. Nicolls, F.Z.S.; two Reindeer (*Rangifer tarandus* ♂ ♀), European, presented by Colonel W. B. Thomson, F.Z.S.; a Beech Martin (*Mustella foina*) from France, presented by Mr.

H. H. Sharland, F.Z.S.; two Herring Gulls (*Larus argentatus*), British, presented by Mr. Joseph White; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. V. H. Dudmesh; a White Pelican (*Pelecanus onocrotalus*), South European, deposited; a Bay Colobus (*Colobus ferrugineus* ♀) from West Africa, purchased; a Large Hill-Mynah (*Gracula intermedia*) from India, received in exchange.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on October 23 = 0h. 9m. 4s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 5046	—	—	23 57 36	+15 33
(2) G.C. 5050	—	—	23 58 52	+ 4 35
(3) 30 Piscium	4	Yellowish-red.	23 56 19	− 6 31
(4) δ Andromedæ... ...	3	Yellow.	0 33 24	+30 16
(5) α Andromedæ... ...	1	Bluish-white.	0 2 42	+28 29
(6) W Cygni	Var.	Reddish.	21 31 53	+44 53
(7) T Aquarii...	Var.	Reddish.	20 44 8	− 5 32

Remarks.

(1, 2) Neither of these nebulæ have yet had their spectra recorded. The first is described as "considerably bright; considerably large; irregularly round; very gradually brighter in the middle": the second as "pretty bright; very small; much elongated; very suddenly much brighter in the middle."

(3) A star of Group II., the spectrum being described by Dunér as "very fine." All the bands 2–9 are very wide, dark, and strongly marked. As the star is a comparatively bright one of this class, a detailed study of its spectrum should be made, special attention being given to the brightness of the carbon flutings, and the presence or absence of dark lines.

(4) Secchi thought this star had a spectrum of Group II., but Dunér and Gothard describe it as one of the solar type, the latter observer, however, stating that it approaches Group II. According to Dunér, D and *b* are strong and dark, and several other lines are distinctly visible. At the place of band 2 (the iron fluting) in Group II. stars there is only a narrow and feeble line. It seems probable that the spectrum greatly resembles that of α Tauri, but as the band in the red has disappeared, it is probably a step higher in temperature. A direct comparison with α Tauri, which can now easily be made, might lead to interesting results as to the changes brought about by an increase of temperature in such a star.

(5) A star of Group IV. The usual observations are required.

(6) There will be a maximum of this variable about October 25. The period is short (120–138 days), and the range is from 5·8–6·2 to 6·7–7·3. The spectrum is an exceptionally fine one of Group II., all the bands being very wide and dark. We do not yet know whether any variations of spectrum accompany the slight changes of magnitude of such a variable as this.

(7) The spectrum of this variable has not yet been recorded. It is one of considerable range (6·7–7·8 to 12·4–12·7), and the period is 203 days. As the magnitude at maximum is not small, the observation of the spectrum should not be difficult. There will be a maximum on October 27. A. FOWLER.

PHOTOGRAPHS OF NEBULÆ.—The current number of *Comptes rendus* (October 13) contains a note by Admiral Mouchez on a photograph of the Ring Nebula in Lyra, obtained at Algiers Observatory by MM. Trépied and Rabourdin. The nebula was given an exposure of six hours, in two evenings of three hours each. The negative obtained is said to be very dense, and a positive copy, enlarged 64 times, has been presented to the Paris Academy. With respect to the photograph, Admiral Mouchez remarked:—" This image of the nebula is certainly the largest that has yet been obtained. It shows, in a very striking manner, the distribution of light in this curious celestial object. We see that a region of maximum light exists at each of the extremities of the minor axis of the elliptical ring. These two maxima are not equal, and in each of the halves of the ring the intensity of the light diminishes gradually up to the extremities of the major axis, where it has the smallest value. These are well-known characteristics of this nebula, and such as may be observed by means of ordinary telescopes. But the photographic observation teaches us other things. In fact, according to the work done at Algiers Observatory, when we photograph this nebula with increasing exposures, the nebulosity does not extend sensibly outside the ring, but spreads more and more towards the centre. On the other hand, when we observe the body in a telescope, we find that the central part of the ring is perfectly separated from the ring itself. The interior of the ring is therefore filled with a material difficult to see, but of which the existence is demonstrated in a certain manner by photography. In fact, the central nebulous star attains an intensity in the present proof nearly equal to that of the feeblest maximum of the ring.

" At the meeting of July 7, 1890, in presenting to the Academy a photograph of the same nebula obtained at Bordeaux Observatory by MM. Rayet and Courty with an exposure of three hours, I pointed out the probable existence of three, and perhaps four, extremely feeble stars which had never been previously indicated, and which formed an almost regular square around the central star in the dark part of the nebula. The existence of at least three of these very feeble stars is now demonstrated with absolute certainty, because of the long exposure, but in the enlarged image they are somewhat confused with the inner edge of the nebula."

At the same meeting of the Academy (October 13), M. B. Baillaud presented a plate of the region about the Ring Nebula obtained at Toulouse Observatory on September 8, 9, 10, and 11, with a total exposure of nine hours. The size of the plate was 9 cm. by 12 cm., and it exhibits about 4800 stars to the naked eye within an area of three square degrees.

STARS HAVING PECULIAR SPECTRA.—In *Astronomische Nachrichten*, No. 2997, Prof. E. C. Pickering notes that photographs of stellar spectra taken by Mr. S. J. Bailey, at Chosica, in Peru, show several stars having peculiar spectra. The following table contains the places of these stars, and a brief description of the spectrum of each:—

Star.	R.A. 1900.	Decl. 1900.	Mag.	Description.
	h. m.	° ′		
Cord. Gen. Cat. 7191	5 59·4	− 6 42	5·8	F line bright.
,, ,, 18859	13 47·7	− 46 39	6·6	F line bright.
,, ,, 19737	14 29·2	− 41 43	2·5	F line bright.
,, ,, 22855	16 48·4	− 44 57	Var.	G and *h* bright.
Cord. Zone Cat. 3612	17 55·1	− 32 42	9·0	Bright lines.
S.DM, − 19° 4854	18 2·1	− 19 25	9·6	Bright lines.
Anonymous	20 9·4	− 39 29	Var.	Bright hydrogen lines.
Cord. Gen. Cat. 29232	21 13·6	− 45 27	6·0	Type IV.

The spectrum of the two stars with "bright lines" is similar to that of the stars discovered by Wolf and Rayet in Cygnus.

The two variable stars in the above list are new. Their discovery resulted from an examination of photographs of stellar spectra at Harvard College Observatory. A comparison of the intensity of the spectrum of the first-named star, situated in Scorpio, with that of others on the same plate, indicated that it fluctuates between magnitudes 7 and 11·4. A similar comparison of the spectrum of the latter variable, situated in Sagittarius, with the spectra of other stars near it, shows that between May and October 1889 it decreased from 8·5 to 10·7 magnitude. Both the stars have spectra of the same character as Mira Ceti and other known variables of long period.

THE PHOTOGRAPHIC CHART OF THE HEAVENS.—The International Committee of the Photographic Chart of the Heavens, will meet at Paris Observatory on March 31, 1891. The last details as to the execution of the work will then be discussed, and it is hoped that all the participating Observatories will be able to begin operations immediately afterwards.

D'ARREST'S COMET.—In the same journal Prof. Krueger points out that the comet discovered by Mr. Barnard of Lick Observatory on the 6th inst., is identical with that of the periodical comet of D'Arrest, for which Dr. Berberich computed an ephemeris (*Astronomische Nachrichten*, No. 2959). An observation at Strasburg on the 10th inst. confirms the identity.

A NEW ASTEROID.—Dr. J. Palisa, of Vienna Observatory, discovered a new minor planet (299) on the 7th inst. Its magnitude was 14.

THE TEACHING OF BOTANY.[1]

THE discussion was opened at great length by Prof. Marshall Ward, who reviewed the whole subject of teaching botany (1 to very young children and in schools, (2) as an academical study at the Universities, and (3) as a special subject for those who are in training for technical and other pursuits which require a knowledge of that branch of science—*e.g.*, foresters, gardeners, timber merchants, &c. He said :—

As I understand it, we may regard the study of botany as approachable from three points of view. We may speak of three ends to be attained : those of (1) elementary botany as a school subject of general education ; (2) advanced botany, as a subject of University or academic training, with a view to teaching and research ; (3) special botany, for various purposes in after life—*e.g.*, those of foresters, planters, agriculturists, horticulturists, brewers, medical men, timber merchants, &c.

This is, of course, a merely arbitrary division for the argument, and not a philosophical classification of the subject-matter of the science of botany.

The next point is the scope of the teaching in each case. I should advocate that all children pass through the preliminary training embraced under No. 1. Not only so, but I would urge the usefulness and importance of elementary botany in schools quite apart from its possible pursuit afterwards.

It seems to me that the time is gone by when we need discuss the direct applicability of teaching in elementary schools : if school training is read to mean education, in the true sense of the word, then there is no necessity for asking that a boy and girl should learn at school only those subjects of which they will make direct application as they grow older. Of course this does not preclude our keeping in mind the relative utility of the various subjects to be taught, but it does—and emphatically—preclude our falling into the error of imagining that a school-subject is of educational value only in proportion to its direct and foreseen utility in the application afterwards. In other words, educating and teaching may be, and often are, very different things.

Now, as I understand it, the nineteenth century has discovered—possibly re-discovered—the truth, that you may impart a wondrous amount of information to a boy or girl without awakening those powers of observing and comparing that lie dormant in the minds of most healthy human beings, and especially when young ; and that many a brilliant boy grows up without being able to draw correct inferences from the phenomena around him, and therefore less able than he should be to hold his own in the world he awakes in.

The peculiarity of the study of elementary botany, properly understood and pursued, lies especially in the interest it arouses in the child's mind, and the ease with which it may be taught, and I would insist and re-insist on the fact that it stimulates and cultivates just those powers of accurate observation and comparison, and careful conscientious recording of the results, which are so needed by us all ; and which, be it understood moreover, come so naturally to children who are not too much under the baneful influence of the mere instruction—the mere information —system.

What I wish to emphasize is that the educational value of this subject is no more to be measured merely by the number and kind of *facts* which the child remembers, than is the educational value of history to be measured by the dates learnt, and the lists of kings and battles committed to memory. History, reading and writing, arithmetic, and other subjects, have an educational value, if properly taught, quite apart from their value as mere accomplishments, which may be granted ; but children are naturally observers, and why this side of their hungry little natures should be starved at the expense of their usefulness in after life has always been a mystery to me.

To those who allow this, and I am happy to see that their numbers are now many, it should hardly be necessary to point out that the elements of botany afford the cheapest, cleanest, and most easily attained means of cultivating in children the powers of observing and comparing direct from Nature, and of leading them to generalize accurately.

Of course no advocacy is needed for good preliminary education in elementary botany in the case of those who are about to continue the pursuit of the subject as an academic study, or for a special purpose, as noted under the headings (2) and (3) ; but a few words may be devoted to pointing out the shocking waste of time and energy, on the part of all concerned, in the prevailing cases where students come up to a University, or other institution for higher education, insufficiently prepared for progressive study.

It is still true that boys and young men leave school without so much as a notion of the real meaning and aims of science : this applies no less to subjects like physics and chemistry, which are professedly much taught in schools now, than to subjects like natural history and botany, which, though avowedly in the curriculum of some good schools, are usually entirely ignored.

There is considerable discussion about the details, but many practical teachers regard such subjects as unfitted for school, because the boys and girls soon cease to be interested, and get lost in the masses of facts and hard names that beset their path : this, to my mind, simply shows where the whole system is wrong, and wrong because the tyrant empiricism still rules the prevailing methods of teaching in schools.

I shall go so far as to say that the only remedy for this state of things is for the teachers to lose that blind worship of facts, as facts, which dominates our school system. I am aware that this lays me open to very serious misconstructions, but I hope to make that all right in the sequel.

I would say to the teachers, therefore, do not fall into the mistake of measuring a boy's progress by the amount of dogmatic information which he imbibes, and splutters forth on to his examination papers, but look to the quality of his understanding of the relations between relatively few and well chosen facts ; and again, pay less attention to the number of facts which a boy observes and of names he remembers, and more to the way in which he directly makes his observations, and intelligently describes them, even if untechnically.

This is, I firmly believe, the only cure for the malady under consideration—*i.e.* it is the prevention of it.

Children in schools are taught most subjects from printed books, and it is not my province to criticize the necessity of this as regards those subjects ; but let a competent teacher try the experiment of making the children read directly from Nature, and he will soon see that the new exercises have a powerful effect. They will stumble, and they will even make stupid mistakes and mispronunciations ; but do they not do so when they are reading—*i.e.* observing and comparing and interpreting —printed words in a book ? Of course they do, and therefore the teacher must not be discouraged by their stumbling and misapprehending when first they have to look at and compare different leaves and flowers, and give forth the articulate sounds which correspond to the impressions created on their minds.

Every weary teacher knows what a blessing is variety in the studies of the class, and it passes my comprehension why advantage is not taken of the splendid opportunity offered by the study of elementary observational botany.

We now come to the important subject of method. How should botany be taught ?

Here, again, I shall consider the subject from the same three points of view referred to above.

(1) Elementary botany in schools should be confined to lessons in observation and comparison of plants, and the greatest possible care should be taken that books are not allowed to replace the natural objects themselves. Indeed, I would go so far as to advise that books be used only as an aid to the teacher, were it not that a judiciously written text-book might be employed later on by even young children as a sort of reading-book.

The chief aids should be the parts of living plants themselves, however, and, in spite of the outcry that may be expected from pedantic town teachers, I must insist that every school might be easily provided all the year round with materials for study. I even venture to think that these materials might be collected by the children themselves : at any rate there should be no difficulty about this in the country.

I will illustrate these remarks by a few examples. The teaching of elementary botany to children should commence with the observation of external form, and might well be initiated by a comparative study of the shapes of leaves, the peculiarities of insertion, their appendages, and so on.

The point never to be lost sight of is that if you teach a child to discriminate, *with the plants in hand and from observation only*, between such objects as the simple, heart-shaped, opposite, ex-stipulate stalked leaves of a lilac, and the compound, pinnate, alternate, stipulate leaves of a rose, you lay the foundations of a power for obtaining knowledge which is in no way to be measured

[1] Discussion at the Leeds meeting of the British Association, in Section D, on September 5.

merely by the amount or kind of information imparted. It does not matter whether the child learns the trivial facts mentioned above, or not, but it is of the highest importance that the child be taught how to obtain knowledge by such direct observation and comparison; and the beauty of it all is that, as is well known, the child will retain most of such information as mere matter of course.

For the main purpose in hand, therefore, it may be contended that any objects would do.

This is no doubt true in one sense, but it should not be forgotten that (1) the mental exercise on the part of the child is best exerted on *natural objects*, to say nothing of the admitted advantages of familiarizing him with Nature, and (2) the parts of plants are so varied, so beautiful, and so common, that he need never lack materials for his simple and pleasant work. Moreover, the parts of plants are clean, light, and easily handled—practical advantages which recommend themselves.

I feel convinced that, if the teachers were not opposed to it, the subject would ere now have been more widely taught; and I shall therefore say a few words in anticipation of difficulties. It has been suggested that materials would be scarce in winter. Not at all. Let the children be familiarized with the observation and comparison of the peculiarities of a sprig of holly as contrasted with one of ivy; or let them be shown how different are the buds and leafless shoots of the beech from those of the oak or the horse-chestnut. Show them how to observe the bud-scales, how to infer the leaf-arrangement from the scars, how to notice the colour, roughness, markings, &c., of the periderm. Or give them introductory notions as to the nature of a hyacinth-bulb as contrasted with a potato-tuber, confining their attention to points which they can make out by observation. Every nut or orange or apple that a child eats might be made interesting if teachers would dare step over the traces of convention, and introduce such ostensibly dangerous articles into class-work—and why not? The doctrine of rewards and punishments is applied more crudely than this in most children's schools!

Be this as it may, there is no lack of material at any season, for children to observe and compare, plant in hand, the peculiarities of shape, colour, insertion, markings, &c., of the leaves, stems, roots, and other parts. The difficulties are supposed to increase when the flower is reached: this is not necessarily the case in the hands of a sympathetic teacher, unless the choice of flowers is very unfortunate and limited.

There is one danger to be avoided here, however. Young children should not be troubled with the difficulties of theoretical morphology: they should be made familiar with the more obvious roots, stems, leaves, tendrils, thorns, flowers, bulbs, tubers, &c., as such, and comparatively, and not forced to concern themselves with such ideas as that the flower is a modified shoot, the bulb a bud, the tendril a leaf or branch, &c., until they have learned simply to observe and compare accurately. Later on, of course, the step must be taken of rousing their minds to the necessity of drawing further conclusions from their comparative observations in addition to recording and classifying them; but if the teacher is really capable of teaching, it will be found that the children begin to suggest these conclusions themselves, and, this stage once reached, the success of the method is insured.

Glimpses of the meanings of adaptations of structure to function soon follow, but they should be obvious and simple at first, and the mistake should not be made of entangling a child in a discussion as to more remote meanings. It should never be forgotten, in fact, that the first steps consist in learning to observe accurately and to record faithfully, comparative exercise being used in addition, both as a check and as a stimulus to the judgment.

The next step is to introduce the methods of the systematic botanist who works in the field, with flower in one hand and lens in the other; and the necessary preliminary and accompaniment of this is to exercise the tyro in describing common plants as a whole. The value of such training in the field can scarcely be over-estimated. As education it is excellent, for it inculcates neatness and accuracy of method, keenness of observation and judgment, and is, moreover, interesting to the young student, as well as healthy in every sense of the word. As preliminary training in all cases where the student will have to pursue the higher branches of botany, or other science, at a University or a technical institution, it is absolutely necessary. There is no need to enlarge on its value to the traveller, the philosopher, and even the *dilettante* who enjoys Nature in his garden, or in the country, or even merely as a reader of books on natural history: just think what enjoyment such a training would add to the lives of thousands who have read Darwin's works imperfectly, and reflect for a moment on what such intelligent appreciation of such writings means to a nation like ours.

(2) The necessities of the higher academic study demand previous acquaintance with the *facies* of a large number of plants—Cryptogams as well as Phanerogams—and it is on this account advisable also that the student has been well trained in field-work: he should, then, be familiar with terms and groups, and be able to observe and compare.

Two chief lines of instruction are open at once to the advanced student, and the first point for discussion is, how far they should be kept separate or together: they are morphology and physiology, for, say what we will, the two are separate studies in their aims and methods.

It is not improbable that the study of pure morphology may be carried too far, as an independent study, and that one-sided views of the nature of plants and their parts may result; but, however true this may be, I take it no botanist will deny that every student should know something of the attainments and aims of modern morphology. If this is admitted, the next point is not likely to be gainsaid—namely, that the study of morphology depends on the study of anatomy and histology, as well as upon that of external form. As we shall see, the same is true, but in a different way, of physiology; but I am concerned at present with morphology only.

It seems to me, in view of these facts, that the advanced teaching must presume an acquaintance with the elements of anatomy and histology; and here, again, I am convinced that if teachers fully recognized how clean, and light, and easily accessible the material is, and how excellent the training of hand and eye on the one side, and of the thinking powers on the other may be made, the difficulties of introducing this elementary laboratory work even into secondary schools would be overcome.

It has been overcome in many cases with regard to chemistry, and there is no reason why it should not be overcome with regard to botany.

However, be it as advanced work at school, or as elementary work at college, the student who proposes to pass on to the higher academic study of botany must face the truth that even an extensive knowledge of the outside forms of plants will not carry him far on the road to be traversed.

Now comes the question hard to answer—Should he study anatomy and histology by selecting the best known and clearest tissues, tissue-elements, &c., from any part of the vegetable kingdom; or should he choose some one plant, and explore the recesses of its structure as thoroughly as possible?

All things considered, I believe the introduction is best effected by the latter method, and for the following reasons. In spite of the drawback that no one plant can be found which shows every tissue or tissue-element at its best, one finds that, by exploring the structure of some one plant as thoroughly as possible, the thoughtful student obtains a better idea of the co-relations of the structural elements than if he seeks for xylem vessels in Maize, sieve-tubes in Cucurbita, collenchyma in one plant, sclerenchyma in another, and so on.

Moreover, the comparative survey can be better carried out, if time permits, by methods such as I advocate.

The next consideration is the selection of the type to be used as a basis. In spite of all its defects, and in anticipation of severe criticism, I maintain that the fern is, on the whole, the most useful and convenient type for the purpose.

No Thallophyte is sufficiently obviously complex in structure to give the student the necessary ideas of co-relations of parts and division of labour; moreover, the lower forms offer peculiar difficulties of observation, cultivation, &c. The moss is too specialized for some purposes, and not sufficiently complex for others. The Phanerogams, on the other hand, although they present the vegetative tissues, members, &c., in the more highly developed and specialized forms familiar to physiology, offer such stumbling-blocks to the tyro in morphology that no one will serve as a suitable type. The pine is the best of those proposed, but even it presents great difficulties to a beginner.

The disadvantages of the fern (taking *Aspidium*) embrace the following: its roots are fine, the stem is short, and the vascular bundles belong to an out-of-the-way type; the spores take a long time germinating, and the prothallus offers difficulties in the way of investigation not easily overcome by a school-boy.

On the other hand, the roots are fairly typical in structure, and introduce the student to the ideas of the root-cap, apical cell, radial bundles, and axial vascular cord. The stem, at least, shows how the vascular bundles have definiteness and continuity of course, in axis and appendages, and these bundles are so large and isolated that an introduction to the notion of their development from embryonic tissue is at least attainable; moreover, the spiral vessels, scalariform tracheides, sieve-tubes, and packing-cells suffice very well—though, of course, in different degrees—to introduce the elements of the xylem and phloem, and I regard it as an advantage to defer the complex idea of cambium.

Elementary notions of other items of complexity appear in the extra fascicular strands of sclerenchyma, while protective hairs, reserve-starch, continuity of leaves and axis, and their origin from the meristem, &c., all serve as foundation stones if properly demonstrated and discussed by the teacher.

But it is the sporophyll on the one hand, and the prothallus on the other, which make the fern so supremely useful as a type. No conceptions in the morphology of plants have been more fruitful than these, and it is of the highest importance that the student really sees and examines these and their accessories for himself.

The beauty of the fern sporophyll as a type for demonstration lies in its being so evidently a leaf, in the sense understood at once by the beginner; then the sorus, sporangium, and spore are evident and easily examined, and even the very useful ideas of the archesporium, tapetum, and the development of the spore can be mastered in the case of the fern with comparative ease.

As for the prothallus, it is admitted to be the most accessible of all, and advantages may be claimed for its independence as a chlorophyll-bearing structure, in spite of its flatttened and somewhat specialized form. The antheridia are curious, no doubt, but the spermatocytes and antherozoids and their development are easily made out so far as general features are concerned: the archegonia are not so typical, perhaps, as those of the moss, but they are sufficiently so to be very useful, and the oosphere, canal-cells, &c., are easily seen by an apt student.

Moreover, I would point out that in the hands of a properly guided student of average intelligence, the teacher can rely upon the fern prothallus for introducing some theoretical notions very difficult to acquire—*e.g.* the gradual separation of the sexual organs, and their withdrawal into the prothallus, and the eventual separation of male and female prothallia, and *their* reduction and withdrawal into the spores, leading to the final specialization of male and female spores, and *their* retention and reduced germination inside the sporophylls, which also become specialized.

I should explain here that I would not propose to carry this explanation of homologies too far at this stage, but my argument is that the foundations for much that is to follow can be laid now with better effect than at any other time. It may be contended that the elementary student cannot possibly understand the Hoffmeisterian morphology until he has mastered the structure of the ovule of the Phanerogam, and that, therefore, it makes no difference in this respect whether he begins at the one end or at the other. I grant this, but my plea is not for the crowning of the student's knowledge of morphology, but for the *foundation* of it, and I lay so much stress on his laying this foundation thoroughly—otherwise it will not bear the weight of the superstructure I should propose to raise on it—that I look for the best type for that purpose; and, bearing in mind that such a type must be convenient, and one wherein the student can find the objects and examine them himself, I believe it has been found in the fern.

It will no doubt be remarked that, in the preceding discussion, I have kept in view more especially the study of morphology as the aim of the young academical botanist, and that it is because the fern is so excellently situated midway in the vegetable kingdom that it forms so good a type for teaching purposes. If it is urged, however, that physiology is the study to be more especially kept in view, then it may be necessary to reconsider the question of a type.

But there are two reasons, to my thinking, for discarding the idea that the study of physiology should be the immediate aim of botanical teaching in schools at present, though I do not despair of its introduction in the near future.

Firstly, the appliances needed, simple as they are in most cases, nevertheless *are* appliances, and will, as matter of fact, bar the way to the study during school life for some time to come; secondly, however much we may insist that the study of the physiology of plants presents its own problems and phenomena apart from those proper to physics and chemistry—and no one can urge this more earnestly than I do myself—nevertheless it cannot be gainsaid that the student of physiology should have a fair acquaintance with elementary physics and chemistry, even at the outset. I am aware that the contrary has been asserted, and that it has been argued that a student may learn to rig up apparatus for demonstrating the respiration of germinating seeds without knowing anything about the properties of oxygen, or what happens when carbon dioxide passes into a solution of barium hydrate, and that he may perform experiments on assimilation knowing no more about starch than that it turns blue with iodine, or on transpiration without understanding anything of the physics of the atmosphere or of water; and I am not prepared to say that such training would be without benefit, but apart from the advantages of the preliminary knowledge of phenomena, every teacher knows how dull is the comprehension of the boy's mind when brought face to face with such experiments devoid of the necessary physical concepts, as they have been termed; and in any case the necessary minimum of physics and chemistry will have to be instilled at the time the experiment is performed.

Secondly, the study of histology—practical acquaintance with the microscope—is a necessary preliminary to physiology, and I am doubtful whether we are at present in a position to demand more than the beginnings of these matters from the schools, though the time will come when it will be disgraceful for a boy to leave school quite ignorant of them.

The study of the fern should be followed by that of the *pine*, and I am not prepared to demand a continued adherence to the type-system beyond this point, except under special and favourable circumstances, such as need not here be discussed. Indeed, I should be quite satisfied if we could depend on school-children learning how to describe plants fairly accurately, and on the boys and girls in secondary schools knowing something more of field botany and how to use a flora, and having a satisfactory acquaintance with the life-history and structure of a fern and a pine. When I speak of field botany as above, it is not intended to exclude an acquaintance with the external appearance of common Algæ, Fungi, lichens, and mosses, &c., though the extent of that acquaintance would necessarily depend upon circumstances.

It must not be overlooked, however, that somewhere between this stage and that of further progress to the higher departments of academic botany, the student will have to do some comparative anatomy and histology, on the one hand, and to master the details of the life-history of certain types of Algæ, Fungi, and Lichens, Muscineæ and Vascular Cryptogams, and look more deeply into that of the Phanerogams.

It depends on circumstances whether the type-system should be followed here or not. If the student is going to specialize in the direction of morphological botany, I am inclined to the opinion that he should steadily pursue the type-system, supplementing his work with comparing special structures selected from allied types as he proceeds. For instance, after working through the life-history of a *Pythium*, he should not need to devote his attention to actually exploring all the details in the life-history of *Mucor* and *Peronospora*, but he should see the sporangia of these, and the haustoria of *P. parasitica;* and again, having worked through the chief stages in the life-history of *Marchantia* and *Funaria*, say, there is no need to insist on the same pursuit of detail in the case of other Muscineæ, but the student might compare with the corresponding structures in his types the sporangia of *Anthroceros* and *Jungermannia*, &c., the leaves of *Sphagnum* and *Polytrichum*, and so on.

If the student is more inclined to the pursuit of physiology, I should prescribe a different course as soon as he has examined a few types of Algæ and Fungi, a moss, and a few Vascular Cryptogams, and I should, moreover, direct his attention at once to the highest plants—the Angiosperms—instead of leading up to them as in the case of morphological studies.

In fact, the system to be pursued for a training in physiology, is to select the best illustrations of the organs, the tissues, and the histological elements of which the functions are to be studied. For the typical root I should go to one plant, but it might be necessary to employ quite another plant for showing root-hairs or root-cap: while selecting the vascular bundles of *Ranunculus repens* or of *Aristolochia* to show certain facts about the bundles as a whole, I might take those of *Cucurbita* for sieve-tubes, those of *Linum* or *Vinca* for bast-fibres, and those of quite other plants for spiral or pitted vessels, &c.

So also with other structures, the training is designed to familiarize the student with the best examples of each structure, and although he must acquire a sufficient insight into the relations of these structures and parts to be able to understand how they work together, and how the functions of some depend on those of others, still his aim is not to follow out their development and relations in space and time, but to deal with their behaviour now and in the mature plant.

Up to a certain point both morphologist and physiologist must work along the same lines: they then diverge, and it is at this period that the more extensive use of books must come in; for the student should now have so *real* a knowledge of the things discussed, that illustrations and information are clear to his understanding. The intending physiologist must put himself in possession of sufficient histology and anatomy to be able to follow the work of the specialists in this domain, and to see what bearings their discoveries have on his branch of investigation: no less must the morphologist follow the special literature, but with his own very different end in view. Both will, of course, have their special literature also.

However, it is obvious that we have now reached a point where no very rigid rules can be laid down, since the advanced academical student is in a position to strike out his own lines, and if he does not display some originality now in his methods, aims, &c., the presumption is that no amount of training on the part of teachers will lead to it. Nay, more than this, it is highly desirable that he should be left alone, for the dormant originality is as likely as not being kept down by the pressure of prescribed studies.

(3) In illustration of what is required in special branches of botanical study, I cannot do better than take the case of the properly-educated forest-student: go where you may, you are not likely to meet with a more representative "practical man" than the trained forest-officer, and consequently his case is peculiarly well adapted for my present purpose.

No one will be so rash as to argue that the botanical training of a forester should err in subordinating a knowledge of trees and wood, the phenomena of germination and nutrition, of growth, &c., to transcendental hypotheses and discussions on the nature of morphological conceptions or on abstruse questions as to the significance of movements of irritability, or the ultimate mechanism of reproduction and the molecular forces concerned in heredity: on the contrary, most people will concur in agreeing with me that the teaching of forest botany should be directed to laying down in the student's mind a good foundation of facts of observation, and showing him how to acquire others, and, further, to training his mind to reason accurately from these facts, so that he may apply his reasoning to the practice which is to be his life's pursuit.

On the other hand, there is a danger which very few people escape when talking on this subject, and that is the danger of supposing that the attention of the forest-student should be confined simply to acquiring and remembering aphoristic statements of facts, and that his accomplishments in this connection measure the fitness of his training. In other words, many so-called "practical men" argue that it is the *quantity of information* which tests the student's progress, and neglect the truth that progress is much more adequately represented by the *quality of the instruction.*

Let us put the case in another way. It is granted that the forest-student must be made acquainted with certain facts of observation, and that he must be informed of important conclusions derived after comparing these facts: it is also granted that his time for training is limited—there is no getting over this, and we need not discuss what the limits are, or why they are so. Now, the problem is, Shall the student devote the whole of this period of training to simply acquiring as many of these facts as possible, the conclusions being limited to those directly applied in the forest; or shall more attention be devoted to the methods of acquiring these facts and of drawing the conclusions from them, and the facts themselves be utilized rather in so far as they are necessary for the training, than as the ultimate aim of that training?

The answer to this question is of the highest importance. If we decide that the chief object of the forest-student's training is to make himself acquainted with the facts themselves, then his whole time will have to be given to such matters as learning the names of plants; the peculiarities of the roots, bark, wood, buds, leaves, &c., of the various trees; the empirical facts as to the relative amount of light, moisture, &c., and the degrees of temperature that each species will bear, and so on; the ascertained growth in height of each species, and the annual increment it exhibits, and so on. It is obvious that, if the student worked continuously for his two years or so of probation, he could make himself or be made acquainted with an enormous mass of such information, but it is equally obvious that he could not nearly exhaust the catalogue of facts. The latter truth becomes still more apparent, however, when we remember that he has to devote his attention to several other branches of study in addition to botany.

But is this the right decision to come to in face of the problem I put before you? I say no! emphatically no! On the contrary, it should be recognized at once that the forest-student cannot acquire more than a small proportion of the facts of his subject while he is in training, and even if he could they would be of no use to him in this shape. The selection being limited, then, it should be the aim of the teacher to direct the student's attention to a selected number of facts (you need have no fear that the list will be a short one) such as throw light upon matters that the student will not be likely to explain for himself, unless he is directed. The facts of the forest will be before him always; why, then, occupy the valuable time of training with an incomplete catalogue of them? There are thousands of other points, however, that he will never know anything about if he does not learn how to observe and infer them while he has the chance with a competent teacher by his side.

Let me give an example. The details of the different modes of germination of the various seeds of trees are numerous, but they can be collated under a few heads. Some seeds, like those of the beech, raise their cotyledons above the surface of the soil, and they become green and expand; others, like those of the oak, remain underground, and devoid of chlorophyll, and do not expand. As sown, however, the beech-mast and acorns are not seeds, but fruits, for each is enclosed in its pericarp. Both agree in having two cotyledons to the embryo; and although the beech seed contains a thin remnant of endosperm, both are usually termed exalbuminous; moreover, the cotyledons have their cells crowded with food-materials consisting chiefly of starch-grains and oil.

The seed of a date-palm, on the other hand, is provided with large stores of food-material in the form of cellulose, as thickening materials to the cell-walls of the endosperm, and it contains a relatively minute embryo, furnished with one knob-like cotyledon only; while the seed of a Scotch pine has a large, fatty endosperm, and a poly-cotyledonous embryo in its axis. The details of germination of the palm and the pine differ, and both in different ways from those of the beech and the oak.

Now it is unquestionable that the forester ought to understand what are called the phenomena of germination; but the inquiry arises, Do we mean by this that he ought to learn the details of the germination of these and a large number of other seeds, or do we mean that he should be made acquainted with what research has shown to be common to all seeds, and then with the chief classes of difference in detail? In other words, is he to be taught generalizations, and shown by a few well-selected examples how they have been and are being arrived at; or is he to be burdened merely with the details themselves, as stated in the words of and on the authority of others? Undoubtedly the former is the true method: the latter is simply empiricism.

Let none fear that the student who is thus taught will learn too few facts—the fetish of the "practical man."

In the first place he cannot proceed without sufficient information to enable him to understand the physiological value of such bodies as starch, cellulose, oils, and proteids; and, without troubling him with the refinements of micro-chemical methods, he will at least have to be made acquainted with the better-known changes which these bodies undergo in the presence of water and oxygen, and with the metamorphoses comprised under metabolism; and here his botanical knowledge comes into intimate relations with his information on elementary chemistry.

But, further than this, how is he to proceed to an understanding of even the outlines of the physiology of germination until he knows the leading phenomena of fermentation on the one hand, and of respiration on the other?

I will not enlarge upon this part of my subject however, but simply assure those unacquainted with the full bearings of these remarks, that there is no paucity of facts in this connection, and that, simply to make himself acquainted with the more salient ones, the student has to devote many hours of careful study in the laboratory.

But he will not understand the process ot germination unless

he is acquainted with the structure of the seed. Here, again, it is not the details of structure of the seed-coats, the nucellus, and the embryo, which differ in each seed taken, that are to tax his memory and disgust his mind, but he must be made familiar with the leading features common to all seeds, and illustrated by a few selected examples. The nature of the seed-coats, the structure of the embryo and its relations to the endosperm, &c., are easily taught, if the teacher knows his art, and the pupil is properly led up to his work; otherwise, I fail to see how the latter is to gain any idea of what a seed is on the one hand, or of how a tree arises from the embryo on the other, and if he does not understand what a seed is, he will never comprehend the process of germination, and he thus misses the best chance of elucidation as to the development of the complex structures of the root, stem, and leaf, &c., which follow.

I have said nothing of the phenomena of growth, moreover, and yet the problems of germination will remain obscure and unintelligible until the student knows something about growth; and this presupposes at least some notions as to the phenomena of cell-division in the embryonic tissue, and of cell-growth and development.

Why say more? It is obvious that these studies lead the one to the other, and the real difficulty is to select the best illustrations and use them to the best advantage.

The forest-student's curriculum, therefore, is not to be regarded as a *narrow* one because he needs only a catalogue of facts, but as a *special* one because the exigencies of his professional time demand his attention to certain classes of phenomena. His early training—would that it began at school—should be in the observation and comparison of plants and their organs: he should then proceed to more comprehensive field-work, and exercises in the description of plants and systematic botany. In selecting his examples special attention should be paid to trees and shrubs, which are commonly neglected by students, and the lens should be always at hand.

Studies in the elements of anatomy and histology must follow, otherwise his progress will be hampered when he has to deal with the subjects of germination, nutrition, growth in thickness and formation of wood, cortex, bark, &c.

Refined histology, special anatomy, and speculative morphology will have to be neglected, nor must he aim at becoming a specialist in taxonomy. His laboratory work must be directed to the end that he may understand the general structure and relations of tissues and organs, otherwise he cannot understand what is known of their functions; that he may have clear ideas as to the parts which yield economic products, otherwise he becomes lost in the long catalogue of these; that he may grasp the salient features in the structure of the different kinds of wood, otherwise he cannot attempt to classify and identify them; that he may know something of the biology of fungi, otherwise he cannot hope to understand the diseases of timber which they cause, or the important scavenging and other work which they perform in the forest, and so on.

It would take too much space and time to enlarge on the pity of the fact that young forest-students come up for training almost totally unprepared for such a curriculum, and especially devoid of the elementary knowledge and powers of observation which they should have received at school: the consequence is, much of their valuable probation period is occupied with acquiring the elementary facts and methods without which they cannot possibly make progress in more special work. Now I should like to see all this altered, and the only way to effect the necessary salutary changes is to have some guarantee that such probationers have a suitable training in elementary botany while they are in the receptive condition of school life.

Let me now suppose the case of a young man destined for a career as a brewer. No one will deny that an essential part of his training should consist in a thorough schooling in the methods of cultivating and separating the various forms of yeast, bacteria, and moulds which are met with in every corner of a brewery, and some of which are the agents on the proper action of which he depends directly, while others are his enemies—for I need not remind you that the fermentation industries all depend on various yeasts, and that the diseases of wine and beer, &c., are due to the interfering action of other microscopic organisms of the nature of yeasts, moulds, and bacteria.

This is all clear, and generally accepted, but I am not so sure that everyone recognizes the fact that the proper study of these fungi and allied organisms is a department of botany; though I am quite sure that many people suppose that it is the province of the chemist to clear up the mysteries of these agents of fermentation and putrefaction.

It requires long practice with the microscope and with botanical methods of investigation to trace the vagaries of even the largest of these ferment-organisms, however; and without implying in the least that some of the methods and results of modern chemistry are not essential in such investigations—for the contrary is really true—I would urge the absolute necessity of a botanical training before the student can grasp the meaning of the problems to be solved.

It is surely childish to reply that the special technical methods of the brewer's microscopist can be acquired without the preliminary training in botany which is here pleaded for. I know they can be acquired, as merely technical processes, and I do not deny that relatively good work has occasionally been done under such conditions by men of genius and industry, who have acquired the botanical knowledge as they proceeded; but the point is that the technologist who has had no training in botany is found groping over problems in a manner he would never have had to do had he a proper view of the nature of plants and plant-life such as a suitable training in the elements of botany would give him.

This training, if commenced at school with exercises on observing and describing plants, and then pursued far enough to give him correct ideas of structure, of the nature and grouping of the histological elements, and of what is best known as to their functions in the physiology of nutrition, growth, and reproduction, would at least save the student from those crude notions as to the so-called physics and chemistry of a yeast-cell or of a fungus-hypha which one so commonly meets with.

I am not in any sense implying that a brewer's technologist should be a botanist, in the accepted meaning of the term: I only urge that he has to confront problems of *physiology* and of *morphology*, over and above his every-day riddles of chemistry and physics; and that even if we concede that physiological actions are nothing more than complex and conditioned physical and chemical actions (and I do not deny this), it is still true that he should be quite clear that this implies much more than it is commonly supposed to imply, and have at least an inkling of what we know as to the complexity of metabolic and other processes.

Now he cannot be clear on this subject unless he knows something of modern plant-physiology; and he cannot follow the teachings of physiology unless he is familiar with what is best known as to the structure of plants, and their general nature. How far he should go in these studies is not for me to limit, but he must at least be able to grasp enough to enable him to understand the progress of the science, and to see how far he is justified in drawing inferences from phenomena observed in other plants and applying his conclusions to the plants he is studying. To attempt to study the behaviour of a yeast-cell, or of a bacterium or mould, without clear ideas as to what is known of the plant-cell generally, seems to me very like obstinately attempting to open a lock in a dark room when you are ignorant of the whereabouts of the lock and have not found the right key.

What I have said with respect to the study of ferment-organisms holds good with regard to the study of what is called bacteriology, and to an even greater extent. For no one is likely to gainsay that such extremely difficult and delicate investigations as those made in the domain of pathology cannot be properly conducted without an intelligent acquaintance with the physiology of parasitic and saprophytic fungi and bacteria, and this being conceded the rest follows as a matter of course.

Yet it is in just this region of special scientific investigation that the grossest sins are committed. It is pitiable to see the wild struggles with facts that have been carried on in the name of bacteriology, and which might have been avoided had the investigators been properly trained in botanical science.

Bacteriology, however, is only one special branch of what is popularly known as the study of germs, and the truth of what has been above stated comes out with yet more startling clearness when we recognize the benefits that have arisen from the study of parasitic fungi and their relations to the diseases of plants. Taking the latter as a special pursuit, it is very difficult to say what should be omitted in a training designed to fit the botanist for investigation. It is only quite lately that pathologists have clearly recognized that the study of the diseases of plants (so important to horticulturists, planters, and foresters) implies by no means a mere acquaintance with the forms of fungi and

systematic relationships, but that it demands, on the one hand, the most patient and refined researches into the life-history of these organisms, and the variations in their biology due to changes in the environment, and, on the other hand, as deep an insight as can be obtained into the normal physiology of the host-plants, and the variations in this due to changes in the environment. In other words, not only must the investigator attack the question of the mutual relations between parasite and host (and he cannot understand these without studying the normal biology of both), but he must also look into the relations of each to a varying physical environment.

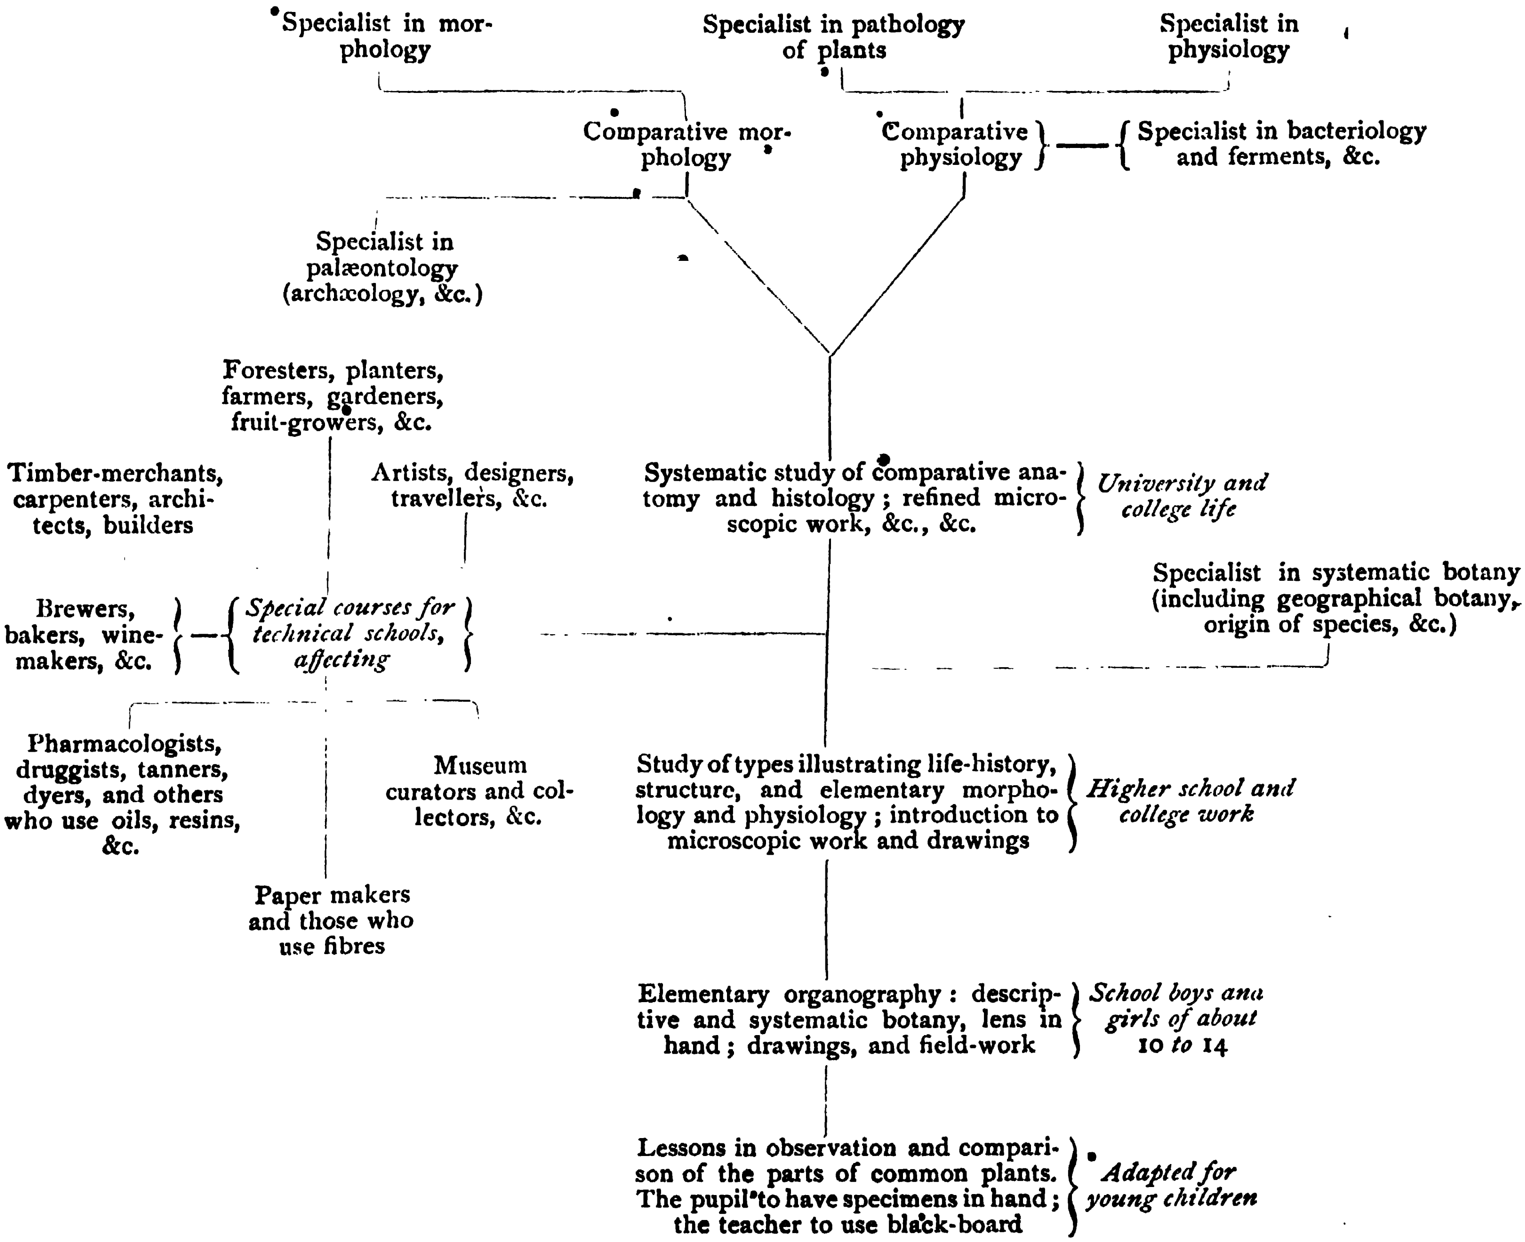
As I said before, it would be hard to say what botanical information can be superfluous in such a training.

But there are other technical pursuits which demand a training in elementary botany, and among these that of the timber merchant, and those of the builder, carpenter, and architect may be grouped together.

It is admitted that these people should understand the nature and properties of timber in the wide sense, and especially of certain kinds of wood in particular. My case is made out quite clearly by the efforts one meets with in various articles and books on timber, designed for the information of those engaged in the trades and professions referred to, and by the lamentable failures in conveying clear instructions, owing to the want of acquaintance with the elements of botanical science.

I maintain that no one can properly understand the markings,

Tabular Résumé of the Various Branches of Botanical Study, as grouped for the preceding argument.



colour, texture, and other technological peculiarities of timber who is ignorant of its structure; and I have had abundance of proof afforded me of the interest taken in this subject by individuals connected with the numerous callings centred around that of the timber merchant—*e.g.* wood-carvers, turners, cabinet-makers, wheelwrights—as well as by archæologists and geologists, who are brought face to face with problems which require an acquaintance with the structure of timber for their solution.

Now, the structure of timber is a very interesting subject if properly approached, but it is a very complex and hopeless subject for one who is unacquainted with the meaning of the four or five histological elements which compose wood, and of their development from the cambium-cells; and, to comprehend these things, the student should know the elements of botany.

But it is not only the properties of timber that have to be understood by the workers and dealers in wood. An important subject, which is coming more and more to the front, is that of the classification and identification of timbers. It is astonishing how cleverly practical experts can find their way through the difficulties which beset those who have to decide upon the value of timber, and the suitability of different pieces of wood for various purposes; but even more astounding is the vagueness of their replies to the very natural question, How do you decide in difficult cases? One thing is clear—the expert bases his conclusions on keen observations of minute details, and yet these observations are not recorded: the whole system is one of empiricism and blind rule-of-thumb guess-work. It serves the purpose in many cases, just as rough measurements by an expe-

rienced eye and hand are often said to serve the purposes of those concerned at the time; but will anyone doubt that scientific accuracy and system would be more reliable? I am aware that "practical men" doubt this, but repeated contact with "practical men" assures one that they pay a heavy penalty in loss of time for their triumphs.

It is repeatedly observable that the "practical man"—the man of experience, in other words—has to spend long periods of time in the acquirement of his unsystematized powers, and the conviction forces itself upon the observer that he could do much more if he were systematically and logically observant, instead of being merely spasmodically so. In other words, he is scientific in so far as his successes go, for in the end it all resolves itself into keenness of observation and comparison; and he would save himself many failures if he were properly trained. How often is it pointed out that such and such a man is unscientific but practical! Well, this resolves itself into a fallacy, for he is really practical in so far as he is scientific in his methods—clumsily so, it may be, and the science in him has been unconsciously acquired and pursued; but it is there, and it is just where his science breaks down that he becomes a mere bungler. This truth need not blind us to the further one that even a bungler occasionally stumbles upon success, but my argument is that his conclusions would be more constantly trustworthy if he pursued a consistent and recorded course of methodical observation and comparison, instead of trusting to the unsystematized impressions from which his keen mind draws the conclusions of of which he is so vain.

It is, to my thinking, one of the most curious problems of the human mind that "practical men" can persist in upholding empiricism, on the grounds that such knowledge as the above is most real and useful. Of course, it is real and useful in so far as it has been acquired during long years of experience in contact with facts; but look at the opportunities lost in this expensive and wasteful training—at the mistakes made and the wrong lines pursued, until correction comes, sharp and merciless because it involves failure. Surely, a better method is to prepare the man to gain his experience at least cost, and to profit to the utmost by his mistakes; and, when all is done, see the equivocal position the "practical man" is put into—his only real knowledge is scientific, and the wild hypotheses and ignorant fallacies to which he is a slave might have become fruitful thoughts, leading him to far higher attainments had he learnt to observe and record, and compare and judge when he was young. Personally, I know no more contradictory being than the one who prides himself on being a "practical man," and is continually throwing at one's head the adage, "An ounce of practice is worth a ton of theory," for at every turn one finds him involved in endless tangles of error, and his ignorance of this is only equalled by the obstinacy with which he contends the contrary.

The second speaker was Prof. F. W. Oliver, who considered the question of botanical teaching only so far as it bears upon the training of medical students. He argued that, since all scientific medicine is based upon elementary biology, it is necessary to bear in mind that, in a course of say fifty lectures, designed for the requirements chiefly of medical students, some things must be sacrificed in order that certain fundamental truths may be driven home. The only questions are, What must go? and what must be retained? And the reply is that much of the study of types, and of such transcendental subjects as the alternations of generations, and so forth, as found in the schedule of the London University, for instance, should be sacrificed in order that the teacher may concentrate his attention on such parts of the subject as are of real importance and interest to the medical student, and others composing large classes. He would go so far as to say that about thirty out of the fifty lectures should be devoted to the organography and elementary physiology of the higher plants; for in that case the teacher is dealing with beings of which everybody knows something, and there is more human interest to the student when the *facies* of the organism is so familiar as is that of common flowering plants. In conclusion, Prof. Oliver pointed out that the responsibility of these matters rests with the examiners and those who draw up such schedules as that of the London University, and laid some stress on the importance of this responsibility.

Prof. F. O. Bower followed, and directed his remarks chiefly to the subject of teaching mixed and elementary classes in a University. He wished especially to deplore the threatened divorce between morphology and physiology, and advocated that such a divorce should be prevented at all hazards. In regard to this, and to some other points, he must differ from Prof. Marshall Ward's conclusions, though he heartily concurred with most of what he had said. He thought that, taking into account the value of the mental exercise, so useful a study as that of morphology should be introduced early, and that the teaching of the main homologies should be insisted upon. With regard to the cut-and-dried schedules now so universal, Prof. Bower was of opinion that, while they protect the weaker teachers, they hamper the strong ones, and he wished very much that more individual freedom should be allowed to lecturers.

Mr. Forsyth was especially interested in Prof. Marshall Ward's remarks on the teaching of botany to children in schools, and described an experiment now being tried in the Leeds Higher Grade School. The children are being taught to bring plants themselves, and to observe them in the field, and the speaker was of opinion that the new departure is a signal success.

Prof. Green spoke very strongly against the "type-system" as now pursued in the teaching of botany. Not only does it occupy too much time, but it is quite a mistake to begin with an unknown and minute object like the yeast plant: not only is the *Saccharomyces* plant a strange object, but the student obtains no adequate notions of its size or properties. He advocated less section-cutting and less work with the compound microscope, and more observation with the simple lens, at any rate until the student is familiar with common objects.

Prof. Hartog differed from previous speakers in thinking it a mistake to be afraid to teach children technical terms, and pointed out that children take very readily to hard names, and are very proud of having acquired them. He also differed entirely from those who advocate that the fern is a good type to begin with: the fern is a difficult type, abnormal in its phloem, its stomata, and other respects, and should be avoided for some time. He thought it much better to select the various tissues and elements from the first, and then pass on to the study of types.

Prof. Hillhouse agreed with Prof. Marshall Ward that technical terms should be introduced carefully and not too early, and considered that botany has suffered in the past from being regarded as associated with hard words. He also advocated that botany affords the best means for introducing students to the use of the microscope.

Prof. Geddes has often found that schools are detrimental to the observing powers of children, and that the real way to interest the pupils is to let them make discoveries for themselves. He advocated the establishment of a botanical garden for every school, and pointed out that very useful notions of geometry can be taught from flowers. Prof. Geddes objected to the type-system for children, and urged that the life of the plant, and not its destruction, should be the aim of teaching. He would interest students in such subjects as insectivorous plants, and so infuse general interest into their studies.

Prof. Johnson remarked that at South Kensington, the home of the type-system, they have for some years past tried varying the order of teaching the several types, and have found that it is best to work down from the higher to the lower plants.

Prof. Marshall Ward having briefly replied, the discussion was then closed by the President.

THE PRESENT POSITION OF THE HYDRATE THEORY OF SOLUTION.[1]

It is but four years since this Section devoted a day to the discussion of the nature of solution;[2] since then, however, the general aspect of the question and the position of the advocates of the two rival theories have undergone such a complete change, that in renewing the discussion we shall run but little risk of going over the same ground which we then trod. At Birmingham, Dr. Tilden opened the discussion by passing in review all the well-known and long-known facts which might by any possibility throw some light on the nature of solution, and those who followed him in the discussion each gave the interpretation of these facts which harmonized best with his own views, and, as the facts themselves were susceptible of several different interpretations, the not surprising result followed that

[1] Paper read before Section B, at the Leeds meeting of the British Association, as an introduction to a discussion on the nature of solutions and the theory of osmotic pressure.

[2] B. A. Report, 1886, p. 444.

each disputant departed holding precisely the same opinions which he had brought with him. Since then, however, each party has obtained, or thinks that he has obtained, positive evidence in favour of his own views; evidence which, if upheld, must be accepted as conclusive, or which must be overthrown before his opponents can claim the victory. The supporters of the hydrate theory claim that the curved figures representing the properties of solutions of various strengths show sudden changes of curvature at certain points, which are the same whatever be the property examined, which correspond to the composition of definite hydrates, and which, therefore, can only be explained by the presence of these hydrates in the solutions; while the supporters of the physical theory, now identified with the supporters of the osmotic pressure theory, claim to have shown that, with weak solutions at any rate, the dissolved substance obeys all the laws which are applicable to gases, and that, therefore, its molecules must be uninfluenced by, and uncombined with, those of the solvent.

In another respect also I may notice that our position to-day differs considerably from what it was four years ago; for instead of having to argue the matter out amongst ourselves, as we did then, we are now favoured with the presence of some of those whose work in this very subject has made their names familiar household words with every physicist and chemist throughout the scientific world.

I propose in the first place to give a brief summary of the evidence which has lately been adduced in favour of the hydrate theory, and in the second place to inquire whether the conclusions drawn from this evidence are invalidated by the important facts elucidated by Raoult, van't Hoff, Arrhenius, and Ostwald.

In one respect the supporters of the hydrate theory start now under a distinct advantage—namely, that their most active opponents do not altogether deny the existence of hydrates in solution, although it is only in the case of strong solutions that they will admit their presence; in such solutions, indeed, it is difficult to see how their presence could possibly be denied. The only means which we have of proving that a liquid is a definite compound is by ascertaining whether its composition remains unaltered by its passage through the gaseous or solid condition—by fractionating it by means of distillation or crystallization. With liquids of comparatively small stability, such as hydrates, crystallization is the only method available; the results of crystallization have led us to conclude that the liquid represented by H_2SO_4 is a definite compound, and precisely similar results must force us to accept the definiteness of the liquids $H_2SO_4SO_3$, $H_2SO_4H_2O$, and $H_2SO_44H_2O$: in the case of each of them the liquid freezes as a whole, and without change of composition; the temperature remains constant throughout the solidification, and any excess of either water or sulphuric anhydride which may have been added may be separated from the pure compound, which alone crystallizes from the mixture. Thus, in the instance taken, between the anhydride on the one hand and water on the other, we have four definite compounds, all existing in the liquid condition.

It does not follow, however, that every hydrate which exists in solution can necessarily be obtained in the solid condition; probably no solution, even when it possesses the exact composition of some existing hydrate, consists of that hydrate only, but of a mixture of it with the products of its dissociation (though the amount of these may be very small); and whether the hydrate or one of these dissociation products crystallizes out on cooling must depend on the relative ease with which the bodies in question assume the solid condition; when the hydrate does not crystallize easily we can hope to obtain evidence of its presence by indirect means only.

Mendeleeff's conclusions respecting the densities of solutions of sulphuric acid and alcohol,[1] mistaken though I believe they were, led to the discovery of the means whereby such evidence might be obtained.

He stated that on plotting out the rate of change of the densities with the percentage composition of the solution (the first differential coefficient) he got a series of straight lines, forming figures with well-marked breaks at points corresponding to definite molecular proportions; but on plotting out the experimental points which he said formed these figures, it is impossible to see any justification for this statement; in the case of sulphuric acid the points and Mendeleeff's drawing of them have been given side by side in the Trans. Chem. Soc., 1890, p. 81, and in the case of alcohol they will be found in the *Zeit. f. Phys. Chem.* VI. i. 10. Crompton then showed[1] from an examination of Kohlrausch's values for the electric conductivity of sulphuric acid solutions that a second differentiation might in some cases be necessary before rectilineal figures with breaks in them were obtained. In my own work on various properties of solutions of the acid I have made free use of this process of differentiation, but I have combined it with, and now nearly entirely rely on, an examination of the original curves with the help of a bent ruler.

In the *Phil. Mag.*, 1890, vol. i. p. 430, will be found rough sketches of the figures representing the densities, contraction on formation, electric conductivity, expansion by heat, heat of dissolution, and heat capacity of the solutions, and in the Trans. Chem. Soc., 1890, p. 338, that representing the freezing-points. In some cases, such as the freezing-points of solutions near 58 and 100 per cent. strength, a mere inpection of the figure enables us to locate the position of abrupt changes of curvature; in general, however, the recognition of such changes is more difficult. On attempting to draw any of these figures with the help of a bent ruler it was found that the whole figure could only be drawn in several sections, and it was also found that each section thus drawn consisted of a single curve of a parabolic nature, although a ruler, when bent by the pressure exerted by the two hands, by no means necessarily forms a parabola; and moreover—and this is the most important part of the evidence—it was found that these figures, though differing so greatly in their general appearance, all split up into the *same* number of sections, indicating the existence of changes of curvature at the *same* points; and, further still, these points corresponded to solutions of definite molecular composition in all cases where the ratio of the acid to the water was sufficiently large to render any such comparison possible; the average difference between the composition indicated by the changes of curvature and that of definite hydrates was only $0{\cdot}057H_2O$. With weak solutions it is, of course, impossible to assert that the changes occur at definite molecular proportions, owing to the smallness of the change in percentage composition which would be caused by an additional molecule of water to each H_2SO_4; but the changes with these weak solutions are of precisely the same character as those with strong solutions, and, unless some strong evidence to the contrary be forthcoming, we must attribute them to the same cause.

To discuss fully the value of the evidence thus obtained would take me more hours than I can now afford minutes; but I think that I may say that these results stand at present unquestioned and uncontroverted, and that unless they can be controverted we must accept the presence of hydrates in solution as having been proved. I may also add that my results with sulphuric acid solutions have been strengthened by obtaining analogous results with solutions of several other substances: that one of the hydrates indicated by them has been proved to exist by isolating it in the crystalline condition: and lastly, that a law governing the freezing-points of solutions has been formulated, according to which we can calculate within experimental error the freezing-point of any solution, whatever its strength may be, provided we acknowledge the existence of every hydrate which my work has indicated; whereas, if we deny the existence of these, the freezing-points calculated according to this or any other law show such divergences from the found values that all semblance of agreement disappears. I am indeed labouring under no small disadvantage in attempting to support the hydrate theory when the greater part of the evidence existing in favour of it is as yet unpublished.

Before proceeding to the second part of my subject I wish to draw attention to the great complexity of some of the hydrates which my work has indicated, as well as to the fact that the indications of sudden changes are nowhere more marked than they are with these very weak solutions. The changes, which are observed in the heat of dissolution curve from 5 per cent. downwards,[2] afford a good illustration of this latter fact; or, again, the freezing-points of weak solutions may be instanced,[3] where the rate of fall from 0 to 0·07 per cent. is a quarter as great again as it is from 0·07 to 1·0 per cent. The complexity of the hydrates indicated is so great that in the extreme cases they must be represented as containing several thousand H_2O molecules, and the suggestion of such complexity will no doubt prejudice many against my conclusions in general; though on what grounds I know not, for we are entirely in ignorance at

[1] *Zeit. f. Phys. Chem.*, i. p. 275; Chem. Soc. Trans., 1887, p. 778.

[3] *Ibid.*, p. 343.

present as to the possible complexity of liquid molecules. It is interesting to note that a similar complexity of molecular grouping must be admitted if we accept Raoult's original statement that one molecule of any substance dissolved in 100 molecules of a solvent lowers the freezing-point of this latter by about $0^{\circ}\cdot63$; for, if this be so, we must assign to the molecules of the various substances entered in the second column of Table I. the magnitude there indicated when they are dissolved in the solvent named in the first column, for it requires that proportion of these bodies to lower the freezing-point of 100 molecules of the solvent by $0^{\circ}\cdot63$; and, amongst these few instances which I have collected from my own determinations, we find molecular aggregates containing as many as 200 of the fundamental molecules, and even this number, I may mention, probably understates the complexity to a very considerable extent; for the depression in this and some of the other cases had to be estimated from that observed with solutions containing as much as 10 gram molecular proportions to 100 of the solvent, and the molecular depression increased rapidly with the strength of the solution: $1000H_2O$ would probably be a low estimate of the complexity of the molecules of water when dissolved in a large excess of the hexhydrate of calcium chloride, a complexity comparable with that of the hydrates, which my other work has indicated, and that too in the case of that very substance which these hydrates contain—water.

TABLE I.—*Molecular Weights of Substances in Various Solvents.*[1]

Solvent.			Dissolved substance producing $0^{\circ}\cdot63$ depression.[2]
$100H_2SO_4H_2O$	...	...	$32H_2O$
,,	...	...	$63H_2SO_4$
$100H_2SO_44H_2O$	...	...	$8H_2O$
,,	...	...	$15H_2SO_4$
$100(CaNO_3)_24H_2O$	...	...	$90H_2O$
,,	...	...	$42Ca(NO_3)_2$
$100CaCl_26H_2O$	...	...	$210H_2O$
,,	...	...	$63CaCl_2$

Now as to the question of how far the theory of osmotic pressure, and the results on which it is based, are antagonistic to the hydrate theory: and let me first define clearly the position which I take in this matter. I do not for one moment call in question any of Raoult's classical work, which is now so familiar to us, nor do I question that these results reveal the existence of a depression of the freezing-point which is approximately and generally constant; and I consequently admit that we can generally obtain an approximately correct value for the molecular weight of the substance by observing the depression which it causes; nor, again, do I wish to question the correctness of the mathematical relationship which van't Hoff and Arrhenius have shown to exist between osmotic pressure, the lowering of the freezing-point, and other properties, provided we accept the fundamental assumptions on which their calculations are based—the truly gaseous nature of dissolved matter, and the dissociation of salts into their ions. But what I do question is that the facts of the case warrant such assumptions, and that the constancy and regularity of the results are so rigorous as to justify the conclusion that the solvent has no action on the dissolved substance, and that there are no irregularities such as would be caused by the presence of hydrates.

According to the osmotic pressure theory, the dissolved matter, so long, at any rate, as it is not present in greater quantity than it would be in the same volume of its gas, if it were gasified under normal conditions, is really in the gaseous condition, and obeys all those laws which apply to gases. According to the hydrate theory this will be but partially true. That the dissolved substance is in a condition comparable with that of a gas, in so far as the separation of its own particles from each other is concerned, must be admitted—indeed, I arrived independently at this same conclusion from a study of thermochemical data; but inasmuch as there is present the solvent, which we believe is *not* an inactive medium, its molecules cannot have the same freedom as if they were truly gaseous, and will, therefore, obey the laws of gases imperfectly only.

It will be well to confine our attention to but one of those properties connected with osmotic pressure, and to select for that purpose the one which has been most fully investigated—the lowering of the freezing-point of a solvent: and the tests which may be applied to assertain whether in producing this lowering the dissolved substance behaves as a perfect gas or not, may be grouped under three principal headings:—

1. Is the molecular depression (*i.e.* that produced as calculated for one molecule dissolved in 100 molecules) constant, independent of the nature of the solvent?

2. Is it independent of the strength of the solution, so long as this strength does not exceed the limits ("gas" strength) above mentioned? (Boyle's law.)

3. Is it independent of the nature of the dissolved substance? (Avogadro's law.)

In the *Phil. Mag.*, 1890, vol. i. p. 495, will be found instances of the variation in the molecular depression which may be noticed by altering the solvent (see also Table I. above). With water in six different solvents it varied between $1^{\circ}\cdot072$ and $0^{\circ}\cdot003$; with sulphuric acid in four different solvents, between $2^{\circ}\cdot15$ and $0^{\circ}\cdot01$; with calcium chloride in two different solvents, from $2^{\circ}\cdot773$ to $0^{\circ}\cdot01$; and with calcium nitrate in two solvents, from $2^{\circ}\cdot5$ to $0^{\circ}\cdot015$; while many instances may be collected from Raoult's data showing that the same substance which acts normally in one solvent may act abnormally (give only half the usual depression) in another. Such variations are so great—from 100 to 35,600 per cent.—that there can be no doubt but that the solvent is *not* that inert medium which the supporters of the physical theory would have it to be, but that it has a very great influence on the results obtained. It must be noted, however, that this objection, though applying to Raoult's original views, does not, or, at any rate, may not, apply to van't Hoff's theory, for according to this theory the nature of the solvent *has* an influence in determining the lowering of the freezing-point, W, in van't Hoff's equation, $\delta t = \frac{0\cdot02T^2}{W}$, representing the heat of fusion of the solvent. But the lowering is according to this equation independent of the nature or the amount of the dissolved substance, so that the two following objections will apply to van't Hoff's theory as well as to Raoult's statement.

Secondly, as to the influence of the strength of the solution. It is remarkable that, although the osmotic pressure theory depends on the behaviour of solutions below a certain strength, no attempt whatever has been made by its supporters to obtain any data respecting such solutions. The data on which their views were founded referred to solutions considerably stronger than the requisite "gas" strength, and though, no doubt, it was convenient to work with data which afforded a ready excuse for any awkard irregularities which might be met with, such data must lack the conclusiveness which is so eminently desirable. The few data which I have accumulated as to solutions of an "ideal" strength can leave no doubt that, even in their case, the depression is not a constant independent of the strength.

A solution of sulphuric acid containing $0\cdot08H_2SO_4$, $100H_2O$ would be of a strength comparable with the gas from the acid if it could be gasified at normal pressure and temperature, and the molecular depression should be constant for all solutions below this strength: it should be represented by a horizontal line such as AB in Fig. 1, whereas the observed deviations from constancy are very great, being represented by the lines marked H_2SO_4; and, moreover, these deviations are by no means regular, and cannot therefore be attributed to imperfect gasification; they possess none of the characteristics of the deviations of gases from Boyle's law. The determinations on which these results are based are very numerous; there are about sixty experimental points on the portion here shown, and the mean error of each point as determined in two different ways was only $0^{\circ}\cdot0005$, a quantity represented by one-tenth of one of the divisions of the paper; the deviations from regularity amount to thirteen times this quantity, and to as much as 16 per cent. of the total depression measured.

The other lines in Fig. 1. represent the deviations from regularity in the case of calcium chloride, calcium nitrate, and alcohol respectively, and these, though they are smaller than in the case of sulphuric acid, are far too great to be attributed to experimental error; and the fact that they occur sometimes in one direction, sometimes in the other, precludes the possibility of attributing them to any constant source of error in the instruments used or in the method adopted.

Remembering that these are the only data which we have at present respecting very weak solutions, we must conclude that the hypothesis that such solutions exhibit perfect regularity is

[1] Other instances of high molecular weights are mentioned by Brown and Morris (Chem. Soc, Trans., 1888), and Gladstone and Hibbert (*Phil. Mag.*, 1889, vol. ii. p. 38).

[2] Determined from the freezing-points of very weak solutions.

wholly untenable; and it must be specially noticed that one of the substances showing these irregularities—alcohol—is a non-electrolyte, in which case the theory of dissociation into ions cannot be brought forward as an explanation of their existence.

It is important to observe that when we pass on to stronger solutions, where the actual magnitude of the deviations becomes so great that they would be revealed by the roughest experiments—deviations of even 70°—and where, I believe, even the supporters of the osmotic pressure theory would not hesitate to attribute them to the disturbing influence of hydrates; these deviations occur in precisely the same irregular manner as they do in the case of weak solutions, and must evidently be attributed to the same cause. The results with alcohol given in Fig. 2 illustrate these irregularities in a very striking manner. It must also be pointed out that, apart from the irregularity of these deviations, their very direction shows that they cannot be attributed to the

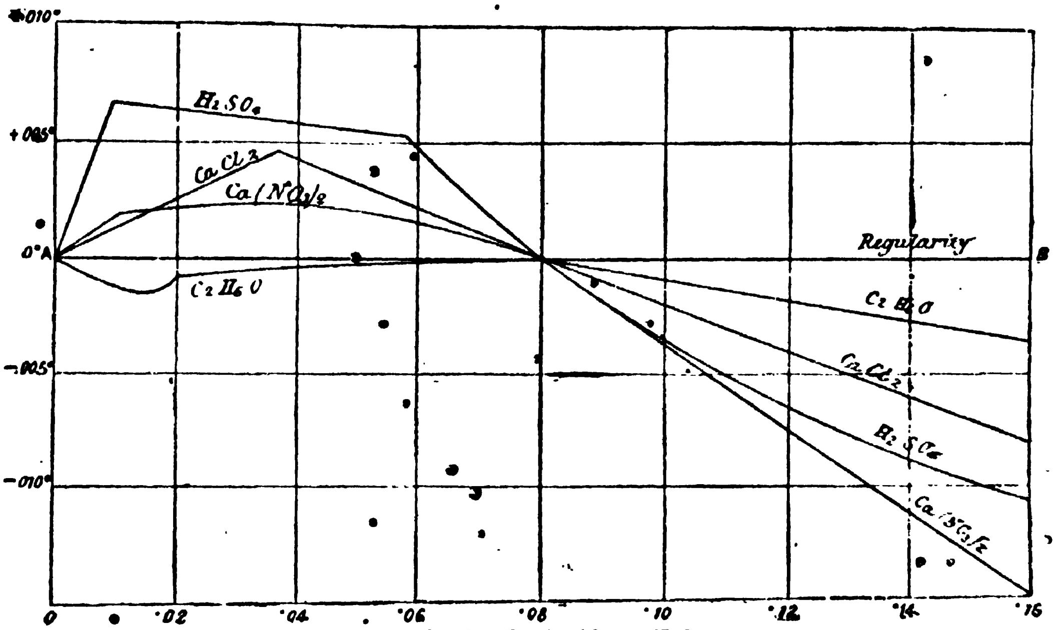

FIG. 1.—Deviation from regularity of the freezing-points of very weak solutions.

dissolved particles being brought within the sphere of each other's attraction, as in the case of the deviation of gases from Boyle's law, for the result of this would be that their attraction on the particles of the solvent would be diminished, and the freezing-point of this latter would consequently be lowered to an abnormally small extent, whereas precisely the reverse is the case in nearly every instance at present investigated: the freezing-points of strong solutions are abnormally *low*. Various instances of this will be found in the *Phil. Mag.*, 1890, vol. i. p. 500, that of sulphuric acid, which is illustrated here in Fig. 2, being by no means the most prominent; while the case of alcohol, now for the first time displayed (Fig. 2), is the only exception which has, so far, been met with, and that is an exception only in the case of excessively strong solutions.

From the instances above mentioned some answer may be obtained to the third question—whether the molecular depression

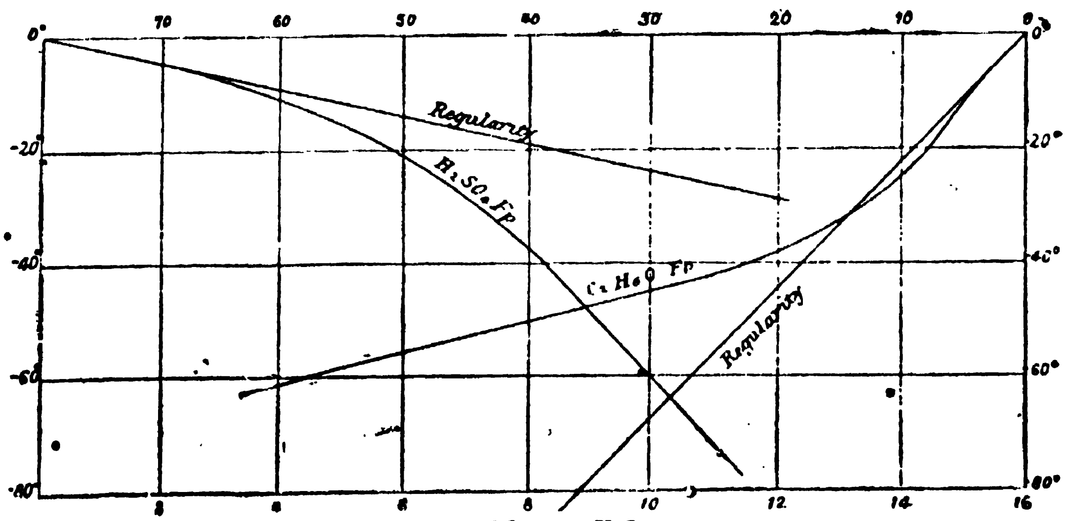

FIG. 2.—Freezing-points of sulphuric acid and alcohol solutions.

is independent of the nature of the dissolved substance. The values obtained with these four substances, taking solutions of a strength corresponding to that of their gases, are:—

Calcium chloride	2°·850
Calcium nitrate	2°·744
Sulphuric acid	2°·313
Alcohol	2°·180

a variation of 30 per cent., which must give an emphatic denial to the idea of absolute constancy; and if we take instances from other substances, where the data available refer to solutions of somewhat greater strength, we find that the very substances on which the idea of constancy was originally founded show variations reaching 60 per cent. (*Phil. Mag.*, 1890, vol. i. p. 492), while in other cases, which I have quoted elsewhere (*loc. cit.*, p. 493),[1] the variation attains the still larger dimensions of 260 per cent.

[1] The depression produced by H_2O in $100H_2SO_4$ is 1°·07 instead of 0°·07 as there given.

To every one, therefore, of the three test questions as to constancy and regularity, the experimental results give an unhesitating negative.

In the instances quoted above the depression actually found for alcohol has been doubled in order to simplify the comparison of it with the other substances. Alcohol belongs to that class of bodies which give just half the value in water that the majority do, and of which there are some instances in the case of every solvent yet examined. The explanations which the supporters of the chemical and physical theories give of these half values differ so radically from each other that it is hopeless to attempt to arrive at any agreement as to the nature of solution till this difference is settled. The chemists say that these half values are in all cases the abnormal ones, just as Raoult did originally, and explain them by representing the molecules of the dissolved substances which give them to consist of two fundamental molecules. The physicists give exactly the same explanation in the case of every solvent except water, but in this case they say that the smaller values are the normal ones and the larger the abnormal, the double magnitude of these being caused by the dissociation of the dissolved molecule into its two ions, whereby two molecules or acting units are formed from every one originally added.

If Raoult's views as to the constancy of the molecular depression can be maintained, the data themselves are conclusive against making this exception in the case of water; for, since the substances which give the lower values are supposed to act normally, it is evident that, if the values given are in any way abnormal, this abnormality must be due to the solvent. Now the values certainly *are* abnormal; they are about 1°·03, whereas the normal value for one molecule dissolved in 100 molecules of other solvents is 0°·63, and the excess can, therefore, only be explained by assuming that the molecules of water are more complex than those of other solvents in the proportion of 1·03 to 0·63, or $1\frac{1}{2}$ to 1; in other words, the water molecules must be $1\frac{1}{2}H_2O$. This view cannot be reconciled with the atomic theory.

Indeed the theory of dissociation into ions is altogether unintelligible to the majority of chemists. It seems to be quite irreconcilable with our ideas of the relative stability of various bodies, and with the principle of the conservation of energy. Of course we know that each ion when dissociated is not supposed to be permanently dissociated, but to be continually combining with its neighbours and separating again from them as in every other case of dissociation; but at any particular moment a very large proportion of them is supposed to be free; a proportion which, according to the very results under discussion, must be very nearly, if not quite, 100 per cent. of the whole; and we have to settle whether it is probable or possible that a decomposition such as this could have been effected by introducing the compound into water. And how can we regard it probable that compounds of such stability and compounds formed with such a development of heat as sulphuric or hydrochloric acid should be thus entirely dissociated by water; still less that these, and all the most stable compounds which we know, should be thus demolished, while all the less stable ones—such as hydrocyanic, sulphurous, boric acids, &c.—remain intact? How can we admit that the more stable a body is, the more prone it is to be dissociated?

And if such a dissociation has occurred it must have been without any absorption of heat, and, consequently, energy must actually have been created. Take one of the simplest instances, that of hydrochloric acid. If anything at all is certain about atoms, it is that the atoms in an elementary molecule are united very firmly together, and that therefore in separating them a very large absorption of heat would occur. To separate 2HCl into 2H and 2Cl would absorb far more than the 44,000 cal. which we know are absorbed in separating 2HCl into H_2 and Cl_2. Yet the supporters of the dissociation theory would have us believe that this separation has actually taken place, not only without any absorption of heat, but actually with a development of 34,630 cal.; that is, that 44,000 + 34,630 + x cal. have been *created*, and that too through the intervention of the water, which has *ex hypothesi* no action whatever.

This difficulty is realized by the supporters of the physical theory, but the way in which they meet it does not appear to me in any way to overcome it. To explain the non-absorption of heat in the dissociation of the salt, they suppose that a charge of electricity combines with the liberated atoms, and, in doing so, evolves an amount of heat exactly equivalent to that absorbed in the separation of the atoms from each other; and a later development of the theory is, I believe, that the atoms, though separated, are still held together by means of these charges, so that the net result is the supplanting of the chemical bond by an electrical bond of a precisely similar value. It appears to me that nothing substantial is gained by such a substitution, and that its occurrence is not merely hypothetical but impossible. Whence come these electric charges, and by what agency are they brought into play? On what grounds can it be maintained that a charge can combine with matter so as to evolve heat, and that the heat so liberated is always exactly equal to that absorbed in the decomposition of the compound? If this equality exists, how can we account for the force which develops the one overcoming the *equal* force which develops the other? and how, again, can we account for the heat developed in the act of dissolving? If, on the other hand, the heat of the combination of these charges is supposed to be equivalent to the heat of combination of the atoms *plus* that of the heat of dissolution, we are met by the objection that the latter is often negative, and that, therefore, the heat of the combination of the charges must often be less than that of the combination of the atoms and molecules, so that the lesser force must be regarded as overcoming the greater.

That free ions exist in solution is supposed to have been proved by a recent observation of Ostwald's, to the effect that the ions may be separated and brought into different parts of the liquid by the proximity of a charged body. The separation of the ions is, of course, recognized by the subsequent liberation of hydrogen, oxygen, acid, alkali, &c., and it is certain that on allowing these to mix and combine heat will be developed, and the salt solution re-formed; and thus, by replacing and removing the charged body, it would evidently be possible to produce an unlimited amount of heat. Now, if the charged body has lost none of its charge, and if no mechanical energy has been expended, this heat must have been produced out of nothing, and the whole ground-work of physical science must be false; whereas, if energy in some form has been expended on the solution, the experiment proves nothing, for there is nothing to show that this energy has not been utilized in bringing about the very dissociation the previous existence of which was in question.

I have already shown that the experimental data prove the absence of that constancy and regularity which ought to exist according to the physical theory, and to place the hydrate theory on unassailable grounds it is only necessary to show that deviations from constancy and regularity are of a magnitude such as might reasonably be assigned to deviations due to the presence of hydrates. That variations of 260 and 36,000 per cent. in the value of the depression—such as are observed by altering the dissolved substance or the solvent respectively—are amply sufficient to satisfy the most exalted views of the influence of chemical attraction, requires, I think, no demonstration, and we may therefore content ourselves with examining the deviations observed when the proportions of the solvent are altered—such deviations as are illustrated in Fig. 1.

It cannot be maintained that the energy of the chemical combination of, say, water with sulphuric acid, is the only reason why the temperature of the mixture of the two must be cooled below 0° before any of the latter will crystallize out; some lowering of the freezing-point will be caused by the mere interposition of the foreign molecules of sulphuric acid between those of the water, and on certain grounds, which I have explained elsewhere,[2] I estimate this mechanical lowering, as I term it, at 0°·56 for each dissolved molecule to 100 of the solvent (a molecule of solvent water being $3H_2O$), a value which, it may be noted, is not far removed from Raoult's experimental value of 0°·63. There is also another source of lowering depending mainly on the heat capacities of the substances concerned, which I term for convenience the physical lowering; but its value, in the case of weak solutions, is very small, and I need, therefore, say no more about it here. Both these lowering causes would exist whether there were hydrates present or not; but if these were present we should get a further depression due to their existence. Any given hydrate would have to be decomposed into the next lower one before it could give up any water for crystallization, and a certain amount of resistance would thus be offered to this crystallization, to overcome which the solution would have to be further cooled.

[1] On the view that hydrates exist in solution, there is no difficulty, as I have shown elsewhere, in explaining the absorption of heat during dissolution, without violating the principle of the conservation of energy.

[2] Proc. Chem. Soc., 1889, p. 149.

The necessary cooling may be estimated in the following way: Supposing the solution to be a mixture, and to be cooled below its normal freezing-point, then, on solidification, the temperature would rise to this point, but if this solidification involved a chemical decomposition which absorbed x cal., the rise of temperature would be thereby reduced, the reduction thus caused amounting to $x \div$ the heat capacity of the solution. As the heat absorbed in the decomposition of the various hydrates of sulphuric acid is known, we can calculate the lowering produced by their presence.

TABLE II.—*Freezing-Points of Solutions of Sulphuric Acid.*

I. Per cent. H_2SO_4.	Calculated.				IV. Found F. p.	Next hydrate.	
	II. Mech.	III. Phys.	IV. Chem.	V. Total.		VII. Calc.	VIII. Found
						Per cent.	Per cent.
0·068	0·0209	0·0	0·0110	0·0347 [1]	0·0354	0·37	0·36
0·362	0·1114	0·0004	0·0248	0·1508 [1]	0·1582	1·43	1·06
1·06	0·3275	0·0044	0·0589	0·4314 [1]	0·4272	3·54	4·02
4·02	1·285	0·071	0·077	1·582 [1]	1·59	8·40	8·59
8·59	2·879	0·388	0·189	3·815 [1]	3·80	18·17	18·49
18·49	6·96	3·23	1·59	11·78	11·83	29·7	29·5
29·53	12 85	18·82	3·50	34·17	34·00	37 5	37·7

In Cols. II., III., and IV., I have given the depression due to the three above-mentioned causes in the case of certain solutions, Col. V. containing their sum; and it will be seen what a small proportion of this total lowering can be attributed to purely chemical causes. With most solutions it does not exceed 10 per cent. of the total, and with weak solutions, such as are generally used in freezing-point determinations—say 5 per cent.—it amounts to considerably less than 0°·1; this, too, in the case of sulphuric acid, where the heat of formation of the higher hydrates is greater than with any other known substance.

The reason, therefore, why the deviations from constancy are so small as to have escaped detection hitherto, and the reason why solutions behave almost as if their chemical nature was non-existent, becomes apparent; but this near approach to constancy and regularity, instead of proving the correctness of the physical theory and giving a death-blow to the chemical theory, is really one of the strongest arguments which can be adduced in favour of the latter. If the hydrate theory is right, the influence of hydrates must often be nearly inappreciable.

But it is not only a general concordance between the found and calculated magnitude of the irregularities which the hydrate theory is capable of affording, but a concordance so exact that the precise value of the deviation at any point may be calculated. In Col. VI. of Table II. are given the observed freezing-points of the solutions, and these show an average difference of but 0°·004 for the three weaker solutions, and 0°·06 for the four stronger solutions, from those calculated (Col. V.). The last two columns exhibit this concordance in a different manner; from the observed freezing-point we can calculate the composition of the hydrates which must exist in the solution (Col. VII.), and these are found to agree so fully with those indicated by the examination of the curved figures representing various properties of the solution (Col. VIII.) that the maximum difference between the two is only 0·48 in the percentage of acid present.

When we can by simple calculations, based on one series of determinations, prove that the hydrates in solution must be the same as those which totally independent experiments have led us to suppose, we have, I think, arrived at proof as nearly absolute as it is possible to conceive; and, if I have succeeded in showing that this proof may be accepted without in any way rejecting the facts on which the advocates of the osmotic pressure theory rely—approximate constancy, approximate regularity, and approximate similarity between dissolved and gaseous matter—I shall feel that I have done far better work than the mere establishment of the hydrate theory, by pointing out a possible *modus vivendi* for both theories almost in their entirety, and by helping to break down that wall of separation between physicists and chemists which is fast crumbling into dust.

SPENCER UMFREVILLE PICKERING.

[1] The actual total has been increased by 10·4 per cent. of its value to give the figures quoted in these five cases, for reasons which will be given elsewhere. Some of the numbers in this table may be subject to slight corrections, as they have been quoted in the absence of the original calculations.

A TEACHING UNIVERSITY FOR LONDON.

THE following letter has been addressed to the Lord President of the Privy Council:—

MY LORD,—We, the undersigned, the President of University College, London, and the Principal of King's College, London, beg leave to address your Lordship in reference to the joint petition from the Councils of our two Colleges for the incorporation of a Teaching University in London, which has for some time been before the Privy Council. Your Lordship had the goodness to receive a deputation from the Councils of our two Colleges in July 1889; and your Lordship then intimated your judgment that the University of London should be allowed a reasonable time in which to propose a new charter in accordance with the recommendations of the Royal Commission on the question of a Teaching University in London. In obedience to this intimation from your Lordship, our Councils have, at the request of the Senate, entered into negotiation with them, and have consented, subject to the satisfactory settlement of some points affecting the Faculties of Law and Medicine, to a scheme for our union with the University, embodying a separate system of graduation for our students in the Faculties of Arts and Science. We desire that power should be reserved in certain events to make similar arrangements in regard to the Faculty of Law. With respect to medicine, the Senate have stipulated that they should be at liberty to make different arrangements, separately from our Colleges; and in the absence of opportunities for conference with the other institutions specially interested in this Faculty, we have not thought fit on this ground to break off the negotiations; but we reserve power to reconsider our position, if arrangements are contemplated by which it would be seriously affected. We claim, further, as essential to the efficiency of our teaching in science, that our medical students, for the purpose of their examination in pure science, known as the "Preliminary Scientific Examination," shall be considered as belonging to the Faculty of Science on the teaching side of the University, and not to a separate Faculty of Medicine.

Having been informed that urgent protests are raised by University Colleges in the country, particularly at Birmingham, against influence being given to London Colleges in the Senate while they are excluded, we beg to remind your Lordship that the amalgamation of the proposed Teaching University for London with the existing University was not our proposal, but has been, thus far, accepted by us in deference to the principal Report of the Royal Commissioners. We consider that, if this amalgamation is effected, we are entitled to a representation on the governing body of the reconstituted University proportionate to our concern in University teaching for London, considered as one of its two spheres of work; and that the nature of the case does not admit of a similar effective representation of institutions elsewhere. If this reconstitution of the existing University should be found, by reason of such opposition, or for any other reason, impracticable, we desire to be replaced in our original position, as petitioners for the establishment in London of a Teaching University upon the lines of our petition presented in 1887, and of the draft charter thereto appended, to which, in that case, we still respectfully adhere.

We have the honour to remain, your Lordship's obedient humble servants,

JOHN ERIC ERICHSEN,
President of University College, London.

HENRY WACE,
Principal of King's College, London.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The election of a Professor of Mechanism and Applied Mechanics, in succession to Prof. James Stuart, will take place on November 12. The names and testimonials of candidates are to be sent to the Vice-Chancellor by Saturday, November 8. The electors are the Vice-Chancellor, Mr. W. Airy, Dr. Besant, Sir F. J. Bramwell, Dr. Cayley, Mr. H. Darwin, Mr. Martin, Dr. Phear, and Lord Rayleigh. The stipend is £700. The Senate has approved a new scheme for the management of the department, under which the Professor is directly responsible for the carrying on of the workshops.

Mr. Chaplin, the President of the Board of Trade, has proposed to the Chancellor that the University should undertake

the systematic education of students of agriculture. The question of funds stands in the way, but a syndicate is to be appointed to consider the question, and it is hoped that by a subvention from the County Councils, or by private benefaction, means may be found for the formation of an agricultural department.

Mr. Wynter Blyth and Dr. Ransome have been appointed additional examiners in Sanitary Science. Between fifty and sixty candidates presented themselves for examination, of whom about forty satisfied the examiners, and have received the University diploma in Public Health.

Mr. J. G. Adami, of Christ's College, has been elected to the John Lucas Walker Studentship in Pathology, in succession to Dr. William Hunter, of St. John's College.

Mr. E. Lloyd Jones has been appointed Demonstrator of Pathology in succession to Mr. Adami, resigned.

Mr. L. R. Wilberforce, of Trinity College, has been appointed Demonstrator of Physics, in succession to Mr. F. Newall, resigned.

The honorary degree of M.A. has been conferred on Dr. Joseph Griffiths, Assistant to the Professor of Surgery, and Pathologist to Addenbrooke's Hospital.

Dr. Donald MacAlister, of St. John's College, has been appointed Assessor to the Regius Professor of Physic.

The following have been nominated as Examiners in Natural Science:—Physics: Prof. Carey Foster, F.R.S., and R. T. Glazebrook, F.R.S. Elementary Physics: Prof. J. J. Thomson, F.R.S., and L. R. Wilberforce. Chemistry: Prof. Liveing, F.R.S., and Prof. Emerson Reynolds, F.R.S. Elementary Chemistry: M. M. Pattison Muir and Dr. Ruhemann. Geology: Prof. A. H. Green, F.R.S., and J. E. Marr. Botany: Prof. D. H. Scott and Prof. J. R. Green. Zoology: Prof. Ray Lankester, F.R.S., and A. E. Shipley. Elementary Biology: Prof. Marshall Ward, F.R.S., and A. Sedgwick, F.R.S. Anatomy: Prof. Macalister, F.R.S., and Prof. Windle. Physiology: L. E. Shore and C. S. Sherrington. Pharmaceutical Chemistry: H. Robinson and E. H. Acton.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 13.—M. Hermite in the chair.—M. Tisserand presented the second volume of his "Traité de Mécanique Céleste," and noted that it deals principally with two subjects—viz. the figure of celestial bodies, and their movement of rotation.—Presentation of the fifth volume of the "Bulletin du Comité international de la Carte du Ciel"; state of progress of preliminary works, by Admiral Mouchez.—On a photograph of the Ring Nebula in Lyra, obtained at Algiers Observatory, by the same author.—On a photograph obtained with a nine hours' exposure at Toulouse Observatory, by M. B. Baillaud. (For the three above communications, see Our Astronomical Column.)—Observation of D'Arrest's comet (rediscovered by Mr. Barnard on October 6, 1890) made at Paris Observatory with the West Tower equatorial, by M. G. Bigourdan. The observation for position was made on October 10.—On the linear equations from partial derivatives, by M. A. Petot.—Vibrations of a platinum wire rendered incandescent by an electric current, under the influence of successive interruptions of this current, by M. T. Argyropoulos. The author has stretched horizontally a platinum wire, 0·70 metre long and less than a millimetre in diameter, and has raised it almost to white heat by means of an electric current. By inserting a commutator in the circuit, the wire immediately vibrated, and became subdivided into a series of waves having well-marked ventral segments and nodes. The number of segments was augmented by very slowly decreasing the tension of the wire. On increasing the tension the number was diminished until the incandescent wire vibrated transversely with a single ventral segment at the middle.—Combinations of cyanide of mercury with lithium salts, by M. Raoul Varet. The following compounds have been prepared: (1) an iodocyanide of mercury and lithium, having the composition $HgCy_2$, 2LiCy, HgI_2, $7H_2O$; (2) a bromocyanide of the same metals, for which the formula $2HgCy_2$, 2LiBr, $7H_2O$ is given; (3) a chlorocyanide of mercury and lithium, of doubtful composition.—Researches as to the best conditions for the preparation of mono-isobutylamine in quantity, by M. H. Malbot.—On a general process for the synthesis of β-ketonic ethers and nitriles, by M. L. Bouveault. The author gives the most general method for the formation of β-ketonic nitriles, and shows that these bodies may readily be transformed into the corresponding ethers. The method is given in sufficient detail, and several examples of its application shown.—Upon the presence and the disposition of trehalose in mushrooms, by M. Em. Bourquelot.—On the lateral nerve of Cyclopteridæ, by M. Frédéric Guitel.—Physiological researches on floral envelopes, by M. Georges Curtel. It is concluded that (1) the flower possesses energetic respiratory and transpiratory functions, superior in general to those of the leaf of the same plant; (2) the assimilation is generally feeble, and cloaked or much diminished by the very intense respiration; (3) the volumetric proportion of carbon dioxide emitted to oxygen absorbed is always small, and less than unity.—On the porphyritic eruptions of Jersey, by M. A. de Lapparent.

SYDNEY.

Royal Society of New South Wales, August 6.—Dr. Leibius, President, in the chair.—Seven new members were elected.—A letter was read from the Committee appointed by the Victorian branch of the Royal Geographical Society of Australasia and the Royal Society of Victoria conjointly, inviting the co-operation of the Royal Society of New South Wales in carrying out the proposed Swedish-Australian expedition to the Antarctic Regions, and stating that Barons Nordenskiöld and Oscar Dickson had promised to defray half the cost of the expedition, providing an equal amount (£5000) was raised in the colonies.—The following papers were read:—On the theory of repetition measures of angles with theodolites, by G. H. Knibbs.—Record of hitherto undescribed plants from Arnheim's Land (part ii.), by Baron Ferd. von Mueller, K.C.M.G., F.R.S.—On the Australian aborigines, varieties of food and methods of obtaining it, by W. T. Wyndham.—On some photographs of the Milky Way, recently taken at the Sydney Observatory, by H. C. Russell, F.R.S.

September 3.—Dr. Leibius, President, in the chair.—The following papers were read:—Record of hitherto undescribed plants from Arnheim's Land (part iii.), by Baron Ferd. von Mueller.—On the application of the results of testing Australian timbers to the design and construction of timber structures, by Prof. Warren.—Exhibits: Enlargement of photograph of a negative of Fresnel's interference bands, for lecture purposes, by Prof. Threlfall; Edison's latest perfected phonograph, by C. L. Garland.

SEEBOHM'S "BIRDS OF JAPAN."

The Birds of the Japanese Empire. By Henry Seebohm. Pp. i.-xxiv., 1-386. (London: R. W. Porter, 1890.)

MR. SEEBOHM'S work on the ornithology of Japan is sure to be welcome to naturalists, as it is always useful to have the avifauna of any country or group of islands monographed and historically brought up to date. In his latest work Mr. Seebohm has incorporated all the results obtained by recent explorers in Japan, and we have now a very fair idea of the birds of this portion of Eastern Asia. The map which accompanies the volume also helps to a better understanding of the relations of Japanese ornithology with those of the adjacent countries. Mr. Seebohm has further made use of the present work to amplify and expound his recently-published "Classification of Birds," so that the work contains his latest views on this important subject. In his original work he gave two schemes of arrangement, giving a preference to the second or "alternative" one. He appears now to have changed his mind, and to have reverted to his original idea ("Classif. B.," p. vii.), with this important modification, that he now places his Coraceiiformes after his Pico-Passeres, ending with Mimogypes (American Turkey Vultures), which lead from the Ground Hornbills (*Bucorax*), and are followed by the Sub-class Falconiformes. There is no doubt that this is a great gain in idea, and we are glad to see that Mr. Seebohm is modifying his first notion, that it is absolutely advisable to reduce the orders of birds to a small number of Sub-Classes. We are of opinion that a still further increase in the number of Orders will have to take place before the scheme works to the satisfaction of ornithologists.

The exigencies of arranging the Passerine Birds in the present work, or at least the bulk of the Palæarctic genera, have obliged Mr. Seebohm to declare himself on the subject of their classification, and this is his declaration:—"With some slight modifications, I have adopted that defined by Mr. Oates ('Fauna of British India: Birds,' i., p. 8), which seems to me to be a distinct advance upon previous arrangements." Mr. Seebohm is under a misapprehension here, unless we allow that his "slight modifications" are intended to entirely subvert Mr. Oates's arrangement by turning it topsy-turvy—a new method of appreciation. The latter gentleman begins with the *Corvidæ*, Mr. Seebohm with the *Turdinæ*, not one of Mr. Oates's families being allowed full rank, but all of them relegated to the position of Sub-families in the family *Passeridæ!* The *Crateropodinæ* (a bad substitute for the *Timeliidæ* (*inæ*) follow the *Turdidæ* in Seebohm's arrangement, whereas in Oates's classification they come after the *Paridæ*, which are by him considered to be a sub-family of the *Corvidæ*. Oates's *Sylviidæ* are separated from his Timaline birds by whole families of *Certhiidæ*, *Sittidæ*, and *Regulidæ*, while in the Seebohmian arrangement the *Sylviinæ* follow the *Crateropodinæ*, and are in turn followed by the *Parinæ*, which contains Gold-crests (= Fam. *Regulidæ* of Oates), Tits (= Sub-fam. *Parinæ* of Oates), Wrens and Creepers (= Fam. *Certhiidæ* of Oates), as well as the Nuthatches (= Fam. *Sittidæ* of Oates). The *Laniidæ* and *Sturnidæ* are the only families which are similarly located by both authors, and in our humble opinion both of them are wrong. If Mr. Seebohm should ever honour us by following any classification of ours in the way in which he has followed that of Mr. Oates, *with slight modifications*, we can only beg to be protected from our friends!

The present work commences with a useful table of the literature relating to the avifauna of Japan, to which may be added a paper by Salvadori and Giglioli, "Uccelli raccolti durante il Viaggio della Corvetta *Vettor Pisani*, &c.," where there are some useful notes on the Scoters (*Œdemia*) and other birds. It seems to us a great pity that, having looked up all his books with so much assiduity, Mr. Seebohm did not think it worth while to publish a full list of references to Japanese birds, which would have been most useful, and is even necessary in a work of this kind. The chapter on the "Geographical Distribution of Japanese Birds" is very interesting, and the subject is worked out with all Mr. Seebohm's accustomed energy and speculativeness, aided by full statistics.

In the third portion of the work, the "Classification and Identification of Japanese Birds," the reader will find a great deal more than the mere title denotes, for, as we have hinted before, the author has seized the opportunity of amplifying all his previous work on the classification of Birds, so that this portion of the book is of the highest interest to ornithologists of every country. We find, however, that some of the woodcuts are not explained in the text, and are apparently added as make-weights to the diagnostic characters of the orders, but the reason for so doing does not seem very clear.

Apart from the omission of the name of the Natural History Museum (Preface, p. iii.) from the list of fourfold obligations which are considered to be due to other Museums of Europe and America, a very uncomplimentary allusion to the work of the present writer occurs on p. 113, under the heading of *Motacilla japonica*. We have no intention of following Mr. Seebohm in his reasoning with regard to this species. He devotes nearly a page to show into what confusion (partly through his own fault, as he admits) these black-backed Wagtails of Japan had fallen, and then he claims to have fixed, in 1884, that Swinhoe's name of *japonica*, bestowed in 1863, must be restricted to the larger form which we re-named *M. grandis*, "a useless synonym," as Mr. Seebohm is kind enough to call it. Nevertheless, we can assure Mr. Seebohm that if Swinhoe intended to give his name of *japonica* to one of the black-backed Wagtails of Japan, it was to the *small* one and not to the *large* one, that he meant it to apply, as a specimen in the British Museum labelled in his own handwriting shows! Swinhoe's name, therefore, is a synonym of *M. lugens*, and neither Mr. Seebohm nor any one else can "fix" the name of *japonica* for the large species. So far from being a "useless synonym," the name of *M. grandis* is the only one which can properly be applied to the latter, and even if Mr. Seebohm's argument had been correct, his manner of criticism is needlessly disagreeable.

In a work like the present, which is nothing if not exhaustive, it is surprising that we can find no reference to *Garrulus lidthi* and *Accentor fervidus*. The only evi-

dence to hand at present is that the former bird inhabits the mountains of the interior of Japan, whilst the *Accentor* may be only *A. rubidus*, but it is at least well to say so. Then again the recent work of Mr. Ogilvie-Grant on *Platalea* and *Turnix* was worth a little consideration. The nomenclature proposed for the latter genus is not adopted, and in spite of the large series of measurements given by Mr. Grant to show that the Eastern race of the common Spoonbill has a longer bill than the Western race, Mr. Seebohm states that he has been "unable to find the slightest evidence of the truth of this statement," a mode of criticism more forcible than exact. We might also ask the author why he persists in calling the Woodcock, *Scolopax rusticola* instead of *S. rusticula*, and the Wild Duck, *Anas boschas* instead of *A. boscas?* Also why does he misspell Linnæus's name throughout the work? Mr. Seebohm has, however, his own ideas as to the fitness of things, and he is in many respects too ultra-conservative for us to hope that our criticism will move him. Otherwise we might ask what is the use of *Eurhinorhynchus* having its spoon-shaped bill, if it is to be merged in the genus *Tringa?* Again, to merge so many species under the genus *Picus*, and again under *Fringilla*, which most of us consider to belong to recognizable genera, tends to fog and confuse the ideas of geographical distribution, and by no means simplifies the study, as Mr. Seebohm would have us believe.

We may add that the work is illustrated by figures from the author's work on the *Charadoiidæ*, but a large number of new cuts are added, which increase the utility of the diagnoses in the classificatory part of the work.

R. BOWDLER SHARPE.

JEANS'S "WATERWAYS AND WATER TRANSPORT."

Waterways and Water Transport. By J. Stephen Jeans, M.R.I., F.S.S. (London and New York: E. and F. N. Spon, 1890.)

THIS volume is intended to give a description of the waterways of the world and water transport, and more particularly means of transport by artificial waterways. Under the heading of "The Transportation Problem," the author deals with the vast improvements made during recent years in roads, both ordinary and rail, and with the great advancement of trade caused by better means of transport during the last hundred years. He shows that, although canals may be considered as belonging to a bygone day, they are now coming again into prominence as a cheap means of transport, and that probably they will in many cases be made the nucleus of a new and better system, under which the great inland towns of Lancashire, Staffordshire, and Yorkshire may practically become maritime places. Chapters ii., iii., and iv. deal with the English river and canal system, and the waterways of Scotland and Ireland, giving an historical account, and showing how most of them in many ways have grown and improved. Readers of this volume will be surprised no doubt at the network of canals in this country: one is accustomed to think of railways as the only means of transport, and to forget the really large traffic carried by canals in many counties. The author tells us of the many continuous lines of water communication between different commercial centres of importance in England, and points out how often it happens that the through routes are rendered useless for really large boats, owing to the locks being shorter or narrower on one section than on another—thus allowing the smallest lock to be the gauge of the boat—down to the very low maximum of twenty-four tons on the canal system between the Derbyshire district and London.

On projected canals the author has much of course to say. The Manchester Ship Canal, which has attracted so much attention, no doubt has been the cause of many similar projects. The Forth and Clyde Canal is designed to enable vessels of considerable tonnage to pass from sea to sea, the present waterway being too contracted to be of much use. The Sheffield and Goole Canal is projected to form an improvement on the present navigation, to enable barges carrying 700 tons, and small sea-going steamers carrying 300 to 400 tons, to come to Sheffield for cargoes, and to serve the South Yorkshire collieries. The proposed waterways from Birmingham to the sea are now being considered in that district. In short, the present tendency seems to be to bring the ship to the manufactory, and thus save the railway charges to the coast for the carriage of the manufactured article.

The book is divided into three sections, the first of which concludes with a good detailed description of the waterways of different countries. Holland, the land of dykes and ditches, appears to have a splendid system of water communication, and the United States has received ample notice at the hands of the author. The waterways of British India are described, and the question of canals *versus* railways in that country is discussed. The author says that "Sir Arthur Cotton has even advocated the summary and indefinite suspension of nearly all railway schemes and works, in order that the attention of the Government might be concentrated upon canals, mainly for irrigation, but also adapted for purposes of navigation." This is all very well from the canal point of view, but it would be interesting to calculate the capacity of canals capable of contending with the present traffic on the railways, excluding any military questions from the subject; and in case of the famine railways, *i.e.* railways built to distribute food as a primary reason for their existence, and where quickness of delivery becomes the all-important consideration, the comparison becomes absurd. Much important work has, however, been done in India by an extensive system of artificial waterways serving the dual purpose of irrigation and navigation, and by careful superintendence the country is greatly improved and enriched by their use.

Section II. of the volume treats of the important subject of ship canals. The greatest artificial waterway constructed up to the present time has been the Suez Canal, and this monument of engineering skill is very properly dealt with first in this section. It is interesting to note that some of the earliest canals recorded were constructed between Suez and the Nile, and these were for some reason allowed to fall into decay. The author gives an excellent account of the construction of the Suez Canal; the political and monetary difficulties encountered by M. de Lesseps in the early days of the company are explained; and the ultimate completion and enormous growth of traffic through the canal are well described. On p. 208, we

are told that "vessels of nearly 200 feet in *width* propel themselves through the canal." This must be a misprint.

Of the Panama Canal we find a good descriptive account. The many early surveys made to locate the best course for such a project are described, and it is interesting to note that as early as the year 1588 the proposal to construct such a canal is recorded. The floating of the original company, the commencement of the works, and the ultimate complete failure of these works, are well described by the author. Everything appears to have happened to seriously hamper the work on every side: political strife on the isthmus delayed the work; an act of incendiarism destroyed a number of buildings erected for the purpose of the canal; and the heavy mortality among the *employés* obtained an unenviable notoriety, and rendered the supply of good men uncertain. Bad as these events proved, the real reason for the ultimate failure of this undertaking must ever be ascribed to the insufficient data obtained of the country and of its geological formation by the company's engineers; the original estimates have proved to be understated and entirely wrong, and the many engineering difficulties must have been practically overlooked.

The Report of the Special Commission appointed in 1889 to inquire into the affairs of the company was published in May, and describes in detail the position of the undertaking. It is estimated that some 30 millions will be required to finish it, so that its ultimate construction does not appear very probable.

The projected Nicaraguan Canal, a purely American project, is also described. The author says:—"The distance from ocean to ocean by the route that has recently received the approval of the United States Government, and is now in course of apparent realization, is 169·8 miles. Of actual canal there will be 40·3 miles, the remaining 129·5 miles being free navigation through Lake Nicaragua, the Rio San Juan, and the valley of the Rio San Francisco."

Chapter xxiii. brings us home again, and deals with the Manchester Ship Canal, a monument of engineering now fast reaching completion. From the excellent description given of these works the reader will obtain a good idea of the undertaking generally.

Chapter xxiv. commences Section III., and deals with the transport problem with special reference to railways and canals. The question of railways *versus* canals is here discussed, and the steady decline of canal navigation from the date of the commencement of railway competition is pointed out. The author says that at that time, "one by one, canals dropped out of the race, and were bought up by the railway companies, either with a view to getting rid of competition, and so securing absolute control over the traffic, or in order to make way for new railway lines." Curiously enough, the *Engineer* of the 3rd inst., in a leading article on this subject, illustrates the above quotation by a reference to the Sheffield Canal, which has been allowed by the present owners—the Manchester, Sheffield, and Lincolnshire Railway Company—to silt up and become nearly useless.

The railways in this and other countries are getting to be considered gross monopolies, and the improvements in the canal navigations are being looked upon as a means of relief. The Manchester Ship Canal is the firstfruits of this feeling on the part of traders and manufacturers, and other ship canals are being talked of.

On the comparative cost of water and land transport the author has much to say. In discussing the relative cost of carriage in the States and in this country, we must not forget that the capital charges per mile on open lines in this country cannot fairly be compared with those in the States, for the reason that the land was in the first instance bought from landowners anxious to obtain the largest sum; the average station buildings and fixed plant are of a far more expensive description; and the kind of traffic carried is of a different type.

The railways in the United States appear to be able to carry goods at a remarkably low rate, no doubt severe competition for the traffic being the reason; at the same time, excluding capital charges and the like, the amount of coal burnt per ton mile in this country is far below that used by the American locomotives.

If traffic is to be moved from town to town at the cheapest rate, it is necessary that it shall be moved in large masses, or trains. It is on this account that the American traffic can be transported by railway cheaper than in this country: were it possible in England to obtain a steady through traffic in any large volume, the weight of trains hauled would certainly increase, and the rates would probably drop in proportion. Canals, when properly managed and with proper appliances, ought to carry heavy traffic with the same regularity as the railways; but as long as they are controlled by the railway companies, they are, in the nature of things, bound to decay and become a secondary means of transport.

The author explains in chapter xxviii. various mechanical means of haulage in vogue at the present time, and then goes on to deal with locks, planes, sluice-gates, and the like. The volume concludes with a chapter on the acquisition by the State of the waterways. The subject is handled in a masterly manner. In this book we have a large amount of information put together in a readable form, and no doubt it will prove very useful to those interested in a very important subject. N. J. L.

SANITY AND INSANITY.

Sanity and Insanity. By Charles Mercier, M.B., Lecturer on Insanity at the Westminster Hospital Medical School, and at the Medical School for Women. The Contemporary Science Series. (London: Walter Scott, 1890.)

TO bring the facts of any department of knowledge before the non-scientific in an easily assimilable form, without offence to the good taste of some one or other section of the community, is by no means so simple a matter as the prolific literature of this class in late years might seem to indicate. It is not every author or lecturer, however able as a man of science, who can thus cater satisfactorily for an omnivorous, but captious and critical public. Every mechanics' institute and popular lecture-room exemplifies this truth—the enthusiasm of the aspirant to public honours in this field is often inversely proportional to his qualifications and actual attainments. The first requisite condition is that the author be

thoroughly and profoundly acquainted with his subject, so that in a popular *résumé* facts should assume their due perspective—that mole-hills be not amplified into a *bizarre* prominence, or that the great mountain tracts encircling the subordinate features of the territory lose not in the distant haze their outlines—in other words, that principles be clearly enunciated, and inductions marshalled in harmonious sequence. The next prerequisite qualification is a keen realization of the obstacles which beset his own path of observation; those knotty points, those complex junctions of thought which cause so much delay in the history of all intellectual effort. The most learned authorities are often the most laboured and tedious exponents of their craft; but we have only to glance at the essays and popular lectures of Clifford, Tyndall, Huxley, or Haeckel, to learn what a degree of excellence is thus attainable by a profound thinker and a cultured mind. It is on account of the rarity of this style of writing that we hail with pleasure the appearance of Dr. Mercier's book, which is an excellent example of the perspicuity with which a cultured mind can delineate an obscure and difficult subject. Dr. Mercier's numerous contributions to psychological literature which have appeared from time to time in *Brain*, *Mind*, the *Journal of Mental Science*, and his book on the "Nervous System and the Mind," are a sufficient pledge of his capacity for a graceful handling of the subject of insanity. After a preliminary sketch of the mechanism of the nervous system, and the modern view of its mental correlate, given in simple but pleasing outline, the author devotes his fourth chapter to a discussion on the "Nature of Insanity," which he defines as a disorder in the *process* of adjustment of the organism to its environment—a disorder not subject to correction. The faulty adaptation of organism to environment is fully considered, and all qualifications in any such definition of insanity are lucidly expressed.

In this chapter above all others the author exhibits his analytic abilities and discriminative capacities to greatest advantage, and the conception of the nature of insanity so framed is to our minds a mental synthesis which has remained unchallenged since first enunciated by Dr. Mercier in 1882. In this connection he makes the trite remark that such process of adjustment is simplified by a simplification of the environment, and hence the major utility of asylum treatment. Undoubtedly, the moral factor will long remain the most important in the treatment of insanity; and here Dr. Mercier would seem at one with Dr. Clifford Allbutt, who with becoming pungency ridiculed the idea of "curing insanity out of the bottle."

The following six chapters are devoted to etiological inquiries, and the causes of insanity are grouped under the headings of heredity, direct and indirect strain, neurotic instability, the laws of inheritance. Reversion and its limitations by the "massive pressure of race heredity" are ably discussed, as is also prepotence in its relations to insanity. The potency of the *moral factor* in the production of insanity, always tinctured with more or less mystery to the laity, is largely developed by the author, and reduced to its simple elementary terms; in fact, the work before us is calculated very largely to remove the repellent aspects of insanity which so long have been created by ignorance and a false appreciation of its nature.

With respect to the community of origin of the religious and sexual instincts, we cannot find ourselves in accord with Dr. Mercier's views; throughout his argument we believe he places undue emphasis on the significance of the sacrificial element. Cogent as are the arguments so frequently used to indicate such lineal relationship, we think equally strong reasons may be advanced to show that the development is along parallel lines of contiguity, rather than the sublimation of the religious out of the sexual element. The concluding five chapters deal with the various forms of insanity; and the vagaries of the insane mind are graphically registered in these short but concise and interesting delineations. We congratulate Dr. Mercier on the production of a work which deserves a widespread popularity.

OUR BOOK SHELF.

A Guide to the Literature of Sugar: a Book of Reference for Chemists, Botanists, Librarians, Manufacturers, and Planters, with a Comprehensive Subject-Index. By H. Ling Roth. (London: Kegan Paul, Trench, Trübner, and Co., Limited, 1890.)

ALTHOUGH published in 1890, it is right to say that this compilation only brings our knowledge down to the beginning of the year 1885. It is intended to have a supplement ready soon, and to bring the work up to date. In the meantime we can speak highly of the evident care and labour bestowed on this volume by the compiler. The arrangement is based on that of Mr. Daydon Jackson's "Vegetable Technology." There is a catalogue of authors, a list of anonymous publications, a list of periodicals, a list of Parliamentary publications, and a chronological table. The first part of the latter is taken from Dr. Falconer's "Sketch of Sugar in Early Times" (1796). The comprehensive subject-index forms a very valuable part of the work. It is arranged in sections as follows:—Bibliography and History, Statistics and General Economy, Illustrations, Geographical Distribution, Chemistry, Origin of Vegetable Sugars (the various plants yielding sugars), Beet Sugar, Cane Sugar, Parasites, and Distillation. It will be easily seen that this guide to the literature of sugar covers practically the whole field in regard to vegetable sugars. It is a work that will prove of much interest to numerous readers having to do with the cultivation and manufacture of sugar, whether derived from the sugar-cane, beet, sorghum, palm, maple, or maize. We only hope the compiler will be encouraged to bring out the promised supplement. During the last five years considerable activity has been displayed in the United States in regard to the production of sugar from sorghum; and there is, besides, the very important fact that the sugar-cane has recently been shown to produce mature seed, and possibly capable of improvement by seminal selection. The literature in regard to this point alone is well worthy of being carefully traced.

D. M.

Practical Plane and Solid Geometry. By I. H. Morris. (London: Longmans, Green, and Co., 1890.)

STUDENTS will find this work to be a most instructive course, arranged in such a way that no external aid will be required. Section I. begins at the very beginning of the subject, and in it there are many problems dealing with lines, areas, use of scales, plans and elevations of solids, sections, &c. Section II. treats of descriptive geometry; and various problems on the projections of lines, oblique surfaces, and solids are given, and thoroughly worked out. The concluding chapter of this section is devoted

graphic arithmetic, in which there are both questions and examples on multiplication, division, addition, subtraction, fractions, involution, &c.

Throughout the book the figures are placed on the right-hand pages, and the text opposite them on the left a very good arrangement. The diagrams and figures are neat and clear, especially the complicated figures required in the drawing of sections of some solids. The exercises have been selected from the papers of the Science and Art Department, College of Preceptors, Oxford and Cambridge Locals, and various Military Colleges. They are carefully graduated, and, when necessary, hints have been added to facilitate their solution.

Madagascar; or, Robert Drury's Journal. Edited by Captain P. Oliver. (London: Fisher Unwin, 1890.)

This book may be divided into three parts: Captain Oliver's introduction and notes, Robert Drury's journal, and a description of the island by the Abbé Rochon. In the first part Captain Oliver tries to prove that the journal is more or less fictitious. At the beginning of the introduction he gives the names of—as he himself says—the best authorities in France, all of whom believe the journal to be true; also a letter which leads him to say that the book was credited in the middle of the eighteenth century. After having quoted these authorities in favour of the truthfulness of the journal, Captain Oliver proceeds to give his own ideas on the subject, which are that the book was written by Defoe from Drury's story, and a great deal of the matter taken out of French books—namely, François Cauche, 1658, and Hacourt, 1661. He then goes on to say that the original journal had a French map, and he regards that also as evidence against Drury. Drury acknowledges himself to have almost forgotten the language and manners of his own country, and, as he was but fourteen years of age when he left, we may take it for granted that he did not know how to draw a map. What then could be more natural, when he had his journal edited, than to take the best map then published, which happened to be a French one, and give it with his journal?

After reading the introduction, one almost thinks that the book is fictitious; but when half-way through the journal, in which every little action is described so minutely, one comes to the conclusion that it is true—at least, that it has not been proved untrue. The journal itself is interesting, but very monotonous.

The description of the island by the Abbé Rochon is very interesting, as it tells all about the first attempts of the French to colonize Madagascar. H. C. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Large Meteors.

The "ball of fire" seen by Mr. C. Randolph at Milverton, Somerset, on October 16, at 12h. 5m., and the "brilliant meteor" observed at Edinburgh, on October 17, at about 15h. (see Nature of October 23, pp. 615 and 620), were probably members of the October meteor shower, which has a maximum on about October 18–20, and a radiant point at 92° + 16° in the extreme north-eastern limits of Orion.

There was also a fine meteor on October 19 at midnight. I was engaged in telescopic observation at the time, and was intently watching a new nebula I had just discovered about 2° N. of the star α Camelopardi, when I became aware of several brilliant flashes which lit up both sky and landscape in a startling manner. Quickly withdrawing my eye from the telescope, I turned towards the direction from whence the flashes proceeded, and saw the end point of a magnificent fire-ball which had fallen in the vapours on the western horizon. It left a bright streak just east of β Aquarii, or from 326° − 8° to 319° − 10°, but this soon died away.

This meteor must have been a grand object to observers in the Bristol Channel and in the western counties of England. The city clocks were striking the hour of twelve when it appeared, and from the direction of its flight it evidently belonged to the well-known Orionid meteor shower.

The new nebula I have referred to is situated at 71° + 68°, and is a fairly conspicuous object in my 10-inch reflector with a power of 60. I watched it for more than an hour for traces of motion, but detected none, so I assume it was not a comet. Since October 19 we have had clouded skies, and I have had no opportunity to re-observe the object.

Bristol, October 24. W. F. Denning.

Extraordinary Flight of Leaves.

The pastoral farm of Dalgonar is situated near the source of the Skarr Water, in the parish of Penpont, Dumfriesshire. The ridge of hills on the farm as per Ordnance Survey is 1580 feet above sea-level. There are only five trees on the farm—two ash and three larch. An extraordinary occurrence presented itself to the eyes of Mr. Wright, my informant, at the end of October 1889, on this farm, which has been narrated to me in a letter received from him, as follows:—

"I was struck by a strange appearance in the atmosphere, which I at first mistook for a flock of birds, but as I saw them falling to the earth my curiosity was quickened. Fixing my eyes on one of the larger of them, and running about 100 yards up the hill until directly underneath, I awaited its arrival, when I found it to be *an oak leaf*. Looking upwards the air was thick with them, and as they descended in an almost vertical direction, oscillating, and glittering in the sunshine, the spectacle was as beautiful as rare. The wind was from the north, blowing a very gentle breeze, and there were occasional showers of rain.

"On examination of the hills after the leaves had fallen, it was found that they covered a tract of about a mile wide and two miles long. The leaves were wholly those of the oak. No oak trees grow in clumps together nearer than eight miles. The aged shepherd, who has been on the farm since 1826, never witnessed a similar occurrence." James Shaw.

Tynron School, Dumfriesshire, October 21.

On the Soaring of Birds.

In answer to my criticism (Nature, September 4, p. 457), Mr. Blix refers (October 16, p. 593) to an article in the *Skand. Arch. f. Physiologie*, in which he has given "an account of the weighty reasons" leading him "to suppose that soaring birds are able to undertake successive alterations of direction with very little loss of *vis viva*." To bring forward reasons, however, tending to show that birds *can* do certain things is no answer to an objection with regard to *how* they do them.

Mr. Blix has thought it superfluous to point out "that the manœuvre of the bird is the same, and the loss of energy thereby equally the same, whether the bird turns in a calm or in a uniform wind," from which it is to be inferred that he had thoroughly grasped the truth of this himself. Why did he, then, propound a theory founded upon what is directly contrary to his own conviction?

It is not easy to see what has led Mr. Blix to suppose that I hold any other opinion, since my letter was written with the intention of pointing out this fact to him.

19 Well Walk, Hampstead, October 23. C. O. Bartrum.

MANNERS AND CUSTOMS OF THE TORRES STRAITS ISLANDERS.[1]

It is not my intention this evening to attempt a special study of any particular institution or series of customs, nor even to discuss the ethnological affinities of the natives inhabiting the islands of Torres Straits.

[1] Friday Evening Lecture delivered at the Royal Institution, by Prof. Alfred C. Haddon, on May 23, 1890.

The comparative study of institutions and customs has led to brilliant suggestions, and has especially thrown light upon obscure facts in our own culture, and given a new significance to observances which, because they are of every-day occurrence, are passed by without comment. This field of inquiry is one which has only recently been systematically tilled, but it promises a rich harvest of unexpected results.

The detailed study of a single tribe or natural assemblage of people has great interest, as it puts one in touch with such varied subjects as the physical, mental, and moral characters of the people; and the tracing out of their affinities requires wide study and careful comparisons. A patient research of this kind always opens up questions of wider import than the initial inquiry.

Neither of these methods will occupy us to-night, as I wish to present before you as vivid a conception as I can of some of the manners and customs of a people small in number but rich in interest. We will consider, therefore, neither a composite image of savages in general, nor of rude customs, but the particular habits of a disappearing people, who thirty years ago were naked, unknown savages, who to-day are British subjects, and who in a very few years will have lost the last remnants of their individuality, and possibly ere long will practically cease to exist—at all events as a distinct people. The dissolving views which I shall exhibit this evening are a fit emblem of the facts which they illustrate.

My Anthropological inquiries in Torres Straits may not inaptly be compared with the methods of the palæontologist, especially in his study of the more recent fossils. Amongst such fossils we find some representatives of existing forms, others slightly different from those we are accustomed to, others again which are quite dissimilar, and often of these only disconnected fragments may remain, and it takes great patience and careful piecing together to restore the latter into any semblance of their former selves; nor should surprise be felt if mistakes are occasionally made in the attempt.

A similar experience occurs to those who study an isolated people which is rapidly becoming modified and is dying out at the same time. Some facts collected from legend and myth precisely resemble the present habits of the natives; others have only lately fallen into desuetude. Lastly, some customs are so dissimilar from anything in our own country, that it is difficult to thoroughly understand them under favourable circumstances; but when these customs are no longer practiced, and but imperfectly remembered, when they have to be described through the unsatisfactory medium of Jargon English, and when one bears in mind the great difference in the mental conceptions of narrator and listener, what wonder is there that disconnected narratives are recorded, or that errors creep in?

Happy is that traveller who has the opportunity of studying existing habits. It was my lot to recover recently lost or fast dying-out customs; our archæologists grapple with the problems of the past; it is the object of all to assist towards a complete History of Man.

Torres Straits, as you are aware, separate New Guinea, the largest island in the world, from Australia, the smallest continent. Although the Straits are eighty miles wide in their narrowest part, yet, owing to the presence of islands and of numerous and often extensive coral reefs, there is only one channel suitable for ocean-going steamers, and that averages a mile in width, and in places is much less.

The islands in Torres Straits may be divided into three geological groups by the lines of longitude 142° 48′ E. and 143° 30′ E.

The islands to the west are composed of old igneous rocks, and are surrounded by fringing reefs. These islands may in fact be regarded as disconnected portions of Northern Queensland. They are fertile, but there is no particularly luxuriant vegetation; doubtless irrigation and cultivation would greatly improve their productiveness.

The central group of islands is composed of low coral islets formed by wind and wave action; the soil is poor, and supports only a scrubby vegetation. Coco-palms grow on some of the islands, and there are occasional mangrove swamps.

The eastern islands, Uga, Erub, and the Murray Islands, are of volcanic origin, and are also fringed with coral reefs. In these the soil is rich and vegetation luxuriant, Uga and a great part of Mer being simply large gardens of coco-palms, bananas, and yams.

It is interesting to find that the inhabitants of the volcanic islands form one tribe, which I term the Eastern Tribe; the Western Tribe occupying all the remaining islands. The customs of the two tribes are different and their languages distinct, so much so that there are only a few words in common, and these are mainly trade words. Four subdivisions of the Western Tribe can be distinguished, the members of each of which inhabit certain intermarrying groups of islands.

Independently of the above-mentioned subdivisions, the islanders were divided into clans, each clan having some animal for its *augŭd* or "totem." For example, in the Western Tribe there were the dugong, turtle, dog, cassowary, snake, shark clans, and so forth. There was supposed to be some relation between the clans and their respective *augŭd*, "all same [*i.e.* similar to] family," as it was expressed to me. A dog-man, for instance, was credited with understanding the habits and feelings of dogs, or a cassowary-man prided himself on having thin shanks like a cassowary, which would enable him to run quickly through the grass. With the exception of the first two clans, no one was allowed to kill or eat the totem of his own clan; if he did, his other clansmen would probably kill him for sacrilege. On a dugong expedition, no dugong-man might keep the first dugong he captured, but he might partake of the rest; the same restriction applied also to the turtle and the turtle clan. If only one dugong or turtle was caught on the first day, the dugong- or turtle-man had to relinquish it; supposing only one was caught on the succeeding day, the account was, so to speak, "carried forward," and there was no *sabi* (*tabu*) on it. The dugong and turtle were too important articles of food for the clan members to be entirely deprived from partaking of their *augŭd*.

The women, or at all events some of them, used to have a representation of their *augŭd* cut on the small of the back. I made inquiries on this point on most of the islands in the Straits, but could only find four old women who had them; these I sketched, and two of them I also photographed.

[Various photographs illustrating the appearance of the natives were then thrown on the screen.]

I have alluded to the fact that different customs characterize the Eastern and Western Tribes; as an example of this I may mention that in the latter tribe the girls proposed marriage to the men, while in the Eastern Tribe the more usual course was adopted.

It might be some time before a lad had an offer; but should he be a fine dancer, with goodly calves, and dance with sprightliness and energy at the festive dances, he would not lack admirers.

Should there still be a reticence on the part of his female acquaintances, the young man might win the heart of a girl by robbing a man of his head. Our adventurous youth could join in some foray; it mattered not to him what was the equity of the quarrel, or whether there was any enmity at all between his people and the attacked. So long as he killed someone—man, woman, or child—and brought the head back, it was not of much consequence to him whose head it was. Possibly a man killed would redound to his greater glory, but any skull was

etter than none, and its possession was recognized as an ider of merit. How much more distinction would a man gain when he could boast of a whole trophy of skulls!

The girl's heart being won by prowess, dancing skill or fine appearance, she would plait a string armlet, *tiapururu;* this she intrusted to a mutual friend, preferably the chosen one's sister. On the first suitable opportunity the sister said to her brother, "Brother, I have some good news for you. A woman likes you." On hearing her name, and after some conversation, if he was willing to go on with the affair, he told his sister to ask the girl to keep some appointment with him in the bush.

When the message was delivered, the enamoured damsel informed her parents that she was going into the bush to get some wood or food, or made some such excuse.

In due course the couple met, sat down and talked, the proposal being made with perfect decorum.

The following conversation is given in the actual words used by my informant, Maino, the chief of Tud.

Opening the conversation, the man said, "You like me proper?"

"Yes," she replied, "I like you proper with my heart inside. Eye along my heart see you—you my man."

Unwilling to give himself away rashly, he asked, "How you like me?"

"I like your fine leg—you got fine body—your skin good—I like you altogether," replied the girl.

After matters had proceeded satisfactorily, the girl, anxious to clench the matter, asked when they were to be married. The man said, "To-morrow, if you like."

They both went home and told their respective relatives. Then the girl's people fought the man's folk, "For girl more big [*i.e.* of more consequence] than boy;" but the fighting was not of a serious character, it being part of the programme of a marriage.

"Swapping" sisters was the usual method of getting a wife. If a man had no sisters he might remain unmarried, unless he was rich enough to pay for a wife with a shell armlet (*waiwi*) or a canoe, or something of equal value. If a youth was "hard up," an uncle might take compassion on him and give one of his own daughters in exchange for a wife for his nephew.

This exchange of girls—a sister for a sister, or female cousin for another man's sister—was an economical method of getting a wife, as one was a set-off against the other. The usual feasting occurred, but the presents were dispensed with, or at all events the purchase-money was saved, and probably there would be no fighting.

When a young man of the Eastern Tribe arrived at an understanding with a girl, he put his *gelar* ("law," *i.e. tabu*) on her, and made arrangements to fetch her away. She kept awake on the appointed night, listening for the preconcerted signal, and they quietly stole away to his parents' house, and the next morning he sent a messenger to say where the girl was. The girl's friends armed themselves with bows and arrows, sharks' teeth fastened on to sticks, and other weapons, and proceeded to the other village; but the fight was not a serious affair. On the same day the girl would be painted red by her future mother-in-law, and clothed with a large number of leaf petticoats; and numerous ornaments would be suspended on her back, these made a clanking sound whenever the girl moved. For some months she remained in the house, and under the constant supervision of her future mother-in-law, the young man residing elsewhere. After say three months, negotiations would commence between the two families, and the girl's relations would come to *taaugwat* (or scrape hands), and presents would be exchanged, and some alteration made in the decking of the girl. After a further probation period of a few months, some friend, in the secret, would engage the young man in conversation, and the bride would steal up behind him with some food she had previously cooked, and, while still behind his back, would thrust it by his side. He, looking round, exclaimed, "Why, that's my woman!" and then hung down his head in shame. Being informed that all was duly performed according to old usage, the couple ate food together, this being the ratification of the contract.

It appears that in the Eastern Tribe marriage was regarded as a state of *tabu*, the man isolating one woman as his exclusive property, for he had powers of life and death over his wife. For several reasons I suspect that the Eastern Tribe has arrived at a slightly higher stage in the evolution of the family than the Western, as the man has a more independent position, and does not live more or less with his wife's people after marriage, as is the custom among the Western Tribe. In both tribes a wife had to be paid for; a canoe, dugong-harpoon, shell-armlet, or articles of equal exchange value, being the usual price.

Manhood is with us a gradual development of youth; with nearly all savages it is a state of privilege, the full advantages of which can be gained only by the observance of special ceremonies.

The growth of hair on the face warned the father that his boy was growing up, and he consulted with other fathers who had sons of about the same age.

"Good thing," he might have remarked; "boy no stop along woman now: he got hair, time we make him man now;" and arrangements would be duly made.

The following information, respecting the former initiation ceremonies, was gained at Tud (usually known as Warrior Island), the natives of which island were probably the most warlike of all the Western Islanders:—

The lads were handed over to their uncles, or to some old man, by their fathers, who then ceased to have any intercourse with them. They were conducted to the *Taiiokwod*, or open space sacred to the men, where no woman or child ever ventured, and which henceforth had for them many deep-rooted associations. The uncles washed the youths with water and then rubbed charcoal into the skin; this being daily repeated till the probation period was over. The lads were covered with mats doubled up like a tent with closed ends, and there they sat the livelong day in groups, without moving, playing, or even speaking. Four large mats stretched across the *Taiiokwod*, the mats belonging respectively to the *Sam* (cassowary), *Umai* (dog), *Kodal* (crocodile), and *Baidam* (shark) clans. For each mat there was a fireplace, the fire being tended by the young men of their respective clans. The old men sat on their appropriate mats, in the centre were the drums, and the dance-masks were placed along one side. Opposite the centre was a small mat, on which sat the chief of the island; for, contrary to the general custom of the tribe, this island had a recognized chief, the result, probably, of their belligerent habits. By the side of where the chief used to sit, a large ovoid stone was pointed out to me; it had a dire significance, for long ago four boys, tired of the irksomeness of the discipline, broke bounds, and meeting their mothers in the bush, asked for food. They were recaptured, and were all killed by the old men with that stone, which was then placed in its present position, as a warning to other youths. The boys of the cassowary and dog clans sat at the end beyond the shark fireplace, and the crocodile and shark boys were placed at the opposite end of the clearing.

Their instructors watched the lads, and communicated to them the traditions of the tribe, rules of conduct were laid down, information in all branches of native lore taught, and thus, generation after generation, the things of the fathers were transmitted to the sons.

The following are some of the rules which I was informed were imparted to the youths by the "old men":—

"You no steal."

"If you see food belong another man, you no take it, or you dead."

"You no take thing belong another man without leave; if you see a fish-spear and take it, s'posé you break it and you no got spear, how you pay man?"

"S'pose you see a dugong-harpoon in a canoe and take it, and man he no savvy, then you lose it or break it, how you pay him? You no got dugong-harpoon."

"You no play with boy and girl now; you a man now, and no boy."

"You no play with small play-canoe, or with toy-spear; that all finish now."

"You no like girl first; if you do, girl laugh at you and call you a woman." [That is, the young man must not propose marriage to a girl, but must wait for her to ask first.]

"You no marry the sister of your mate, or by and by you will be ashamed; mates all same as brothers." [But "mates" may marry two sisters.]

"You no marry your cousin; she all same as sister."

"If anyone asks for food, or water, or anything, you give something; if you have a little, you give a little; if you have plenty, give half."

"Look after your mother and father; never mind if you and your wife go without."

"Don't speak bad word to mother."

"Give half of all your fish to your parents; don't be mean."

"Father and mother all along same as food in belly; when they die you feel hungry and empty."

"Mind your uncles, too, and cousins."

"If woman walk along, you no follow; by and by man look, he call you bad name."

"If a canoe is going to another place, you go in canoe; no stop behind to steal woman."

"If your brother is going out to fight, you help him; don't let him go first, but go together."

Who will say, after this, that the Torres Straits Islanders were degraded savages?

At length the month of isolation expired, and for the last time the uncle washed the lad; he then rubbed him with scented leaves, and polished him up with oil. Then he was decorated with armlets and leglets, breast-ornaments, and possibly a belt, his ears ornamented, and a shell-skewer passed through his nose; bright-coloured leaves would be inserted in his armlets, and his hair rolled into the approved string-like ringlets. So they "make him flash—flash like hell—that boy."

The afternoon of the eventful day was occupied in this congenial task, and at nightfall all the lads who were being initiated were marshalled by their uncles behind a large mat, which was held vertically. In this wise they marched to the village until they arrived at an open space where a mat was spread on the ground before a circle of friends and relatives. When the approaching party reached this mat the lads seated themselves upon it, and then the screening mat was lowered. Suddenly, for the first time for a month, the fathers and female relatives saw the boys, and great were the crying and shouting and exclamations of delight at the brave show. With tears the mothers cried out, "My boy! my boy!" and they and other elderly female relatives rushed up to them and fondled and caressed them, and the mothers surreptitiously put dainty morsels by their boys.

Sitting with legs crossed under them and down-turned faces, the boys neither moved nor exhibited the least emotion, for now they were men.

Less precise is my information respecting the corresponding rites of the Eastern Tribe. So far as I could gather, there were in Mer, the largest of the Murray Islands, two important ceremonies, which we may term the initiation and recognition ceremonies. For the first the lads were assembled near a sacred round house, or *pelak*, in which the awe-inspiring masks were kept. The ceremony was conducted by three *zogole*, or sacred men, and their *tamileb*, or attendants. The latter arranged themselves in a double row, from the *pelak* to the place where the boys were assembled, and, holding long sticks, performed certain movements. Slowly the dread apparition advanced; the chief *zogole* came first, wearing a huge mask with human features and a beard of jaw-bones; the second *zogole* steadied this mask with a rope; the third *zogole* wore a long mask, shaped like a shark. Then for the first time the names of these masks were revealed to the lads—BOMAI and MALU. These were the sacred names which it was not lawful to communicate to the outsider, death to both being the penalty. Their collective name of *Agud* was, however, known to all.

I can only allude to the customary food-offering presented to the *zogole*, and the course of instruction instilled into the youths, one item of which was the narration of the legend of Malu, and must pass on to the recognition ceremony. This function took place in the afternoon on the sand beach outside the village of Las. A great concourse of people was assembled—men, women, and children—the newly initiated lads occupying the front row.

First four men of the dog-clan played about in pairs. (I may here parenthetically remark that it took me a fortnight's work to glean what little information I have respecting these two ceremonies. On one occasion I induced a number of men to rehearse some of the dances for me on the actual spot where they were originally performed, in order that I might gain a clear comprehension of them. One of my photographic "studies" I now throw on the screen.) The dog-men were followed by pigeon-men, who danced and beat their chests; later, whirling along the strand, came a body of dancers, circling from left to right as they advanced, an outer ring with sticks, an inner ring brandishing stone clubs, and possibly some drum players in the centre. Lastly, the three *zogole* appeared, completely covered with white feathers, and each carrying five wands. Although seen by the women, their identity was supposed to be unknown.

This was the final function, and was followed by the ever-recurring feast. Thenceforth the lads took standing as men.

Strangely enough, at neither Tud nor Mer could I discover that the bull-roarer was employed at these ceremonies. The widespread use and sacred character of this simple instrument has been emphasized by Mr. Lang in one of his charming essays. Knowing its universal distribution in Australia, I was not surprised to find that in Muralug, or Prince of Wales Island, which lies close to Cape York, its use was associated with the initiation of the lads. It was only by speaking in a low voice to the chief of the island and his son Georgie, whose photograph you have already seen, and by assuming more knowledge than I actually possessed, that I could induce them to admit of its being employed. Cautiously looking round to see that no one was near, its name, *wanes*, was whispered to me. After much persuasion, a model of one was made for me, on the express understanding that I should not show it to any woman on the island; and I did not. It is now in the British Museum. All that I could gather was that it was whirled in the bush and then shown to the lads. Death was the penalty to both if a man exhibited it to a woman, or to anyone who had not been initiated.

Great was my surprise when, shortly afterwards, I saw the Saibai boys who were staying at the mission station on Mer, playing with bull-roarers identical with the one with which I had been so secretly intrusted. The most sacred emblem in one island was a toy in another. In case some of you may not be acquainted with this most interesting implement, I have brought one of these bull-roarers.

From these important initiation ceremonies we may

pass to others which had a less sacred significance. All the native ceremonies were associated with processions, or with movements of a less regular character, the performers of which were invariably specially dressed for the occasion—usually there was a special costume for a particular rite, one distinguishing feature of which was the wearing of masks or head-dresses. It is convenient to describe these functions as dances; and a series can be traced extending from the most sacred initiation and funeral dances on the one hand, through the seasonal dances to the war and ordinary festive dances on the other.

Profanation of the initiation or of the funeral ceremonies was punished with immediate death. In some instances, at all events, dance-masks could only be worn at the appropriate festival; even the casual putting on of one was supposed to cause slow but certain death. It was my good fortune to witness a seasonal dance at Thursday Island. This was anticipatory of the fishing season during the north-west monsoon.

The men were clothed with a petticoat made of the shredded sprouting leaves of the coco-palm, and adorned with various armlets and leglets; but the striking part of the costume was the mask, of which the lower portion represented a conventional crocodile's head, surmounted by a human face; above this was a representation of a saw-fish, some five feet in length, and overtopping all was a long red triangular erection decked with feathers. The ceremony was called the *Waiitutu kap*, or "saw-fish dance." The actual dance consisted of two men at a time coming out from behind a screen and going through their simple evolutions to the monotonous accompaniment of the drum and a lugubrious chant.

More varied was the costume of the secular dance. All their bravery was donned. The effective head-dress of egret's feathers, or the cassowary coronet, framed the face, a shell skewer pierced the nose, breast ornaments, coco-palm leaf petticoats, armlets, leglets, ornaments or implements carried in the hand, all went to make up a picture of savage finery. Here, too, the women were occasionally allowed to participate, though of course both sexes never danced together. When women were allowed to be present at the more important dances, they were merely spectators.

The large canoes of the Torres Straits Islander of former times must have been very imposing objects when painted with red, white, and black, and decorated with white shells, black feathers, and flying streamers; and not less so when actively paddled by a noisy, gesticulating, naked crew, adorned with cassowary coronets, shell ornaments, and other native finery; or swiftly sailing, scudding before the wind with mat sails erect.

The body of a canoe is a simple dug-out, on to the sides of which gunwale boards are lashed. There is a central platform supported on a double outrigger. The thwart poles of the outriggers are usually six feet apart, and extend to some ten feet beyond the stem of the canoe; a doubly-pointed float is attached to the ends of the thwart poles on each side. Receptacles are built into each side of the platform for the storage of bows and arrows, fishing gear, water-bottles, and other belongings.

The sails are two in number, and are oblong erections of matting placed in the bows, some twelve feet in height, and each about five feet wide. The mats are skewered on to two long bamboos, which support the sails along their length; a bamboo stay also serves to keep the sail upright.

The longest canoe I measured was nearly sixty-eight feet in length. A stone lashed on to a rope is kept in the bow for an anchor. When sailing, a man stands in the stern holding the steering board.

The canoes are made at the mouth of the Fly River, in New Guinea, and are fitted with but a single outrigger, as theirs is only river navigation. I was informed that it was at Saibai that the canoes were re-fitted, this time with two outriggers, and an attempt at decoration was made, but the latter having a purely commercial significance was rather scant. The ultimate purchasers ornamented their canoes according to their fancy, as they usually prided themselves on having fine canoes.

I was much puzzled when I first went to Torres Straits by occasionally seeing a canoe with a single outrigger. I afterwards found it belonged to a native of Ware (one of the New Hebrides) residing at Mabuiag, and that he had re-outrigged a native canoe according to the fashion of his own people. When I was staying at Mabuiag some natives of that island were fitting up a canoe in imitation of this one. Here a foreign custom is being copied; how far it will spread among the Western Tribe it is impossible to say; but, strangely enough, the Eastern Tribe has entirely adopted an introduced fashion, and I did not see a solitary canoe with a double outrigger. It would be tedious to enter into a comparison between these various canoes. In the Eastern Islands the platform baskets are absent, and European sails are in universal use—mainsail, foresail, and jib. Among the Western Tribe, European sails have not yet quite supplanted the original mat sails. Throughout the Straits the canoes are not decorated in the old style. It was in Mabuiag alone that I found two canoes which were more or less decorated. Utilitarian ideas are now two widely spread for the æsthetic faculty to be indulged in.

I have dwelt at some length on this subject, as it is important to record all transitions. As an example of how rapidly and completely some changes occasionally come about, I may mention that at Mer, one of the Eastern Islands, some, at all events, of the young men did not appear to know that there had been a change in the rig of their canoes.

But, after all, the most interesting feature in connection with the canoes is the method by which they are purchased. I have previously mentioned that they were made on the mainland of New Guinea on the banks of the Fly River. Supposing a native of Muralug (Prince of Wales Island, the island which is nearest to Cape York) wants a canoe. He sends word, say, to a relation of his in Moa, for the inhabitants of these two islands often intermarry. The latter sends a message to the next island of Badu. A Badu man passes on the word to Mabuiag (these two also were intermarrying islands); the Mabuiag native informs a friend in Saibai, who in turn delivers the message at Mowat, on the mainland of New Guinea, or Daudai, as the islanders call it, thence the word passes along the coast till it reaches the canoe makers. As soon as the canoe is ready it retraverses the route of the order, being handed on from place to place, and island to island, until it at length reaches its destination. Should, however, there be a new canoe for sale on any of the intermediate stations, this might be sold, and thus obviate the tedious delay of waiting for one to be made to order. Another trade route is through Nagir and Tud to Mowat. The Murray Islanders send to Erub, and the natives of the latter island trade directly with Parem and the mouth of the Fly River. The most remarkable feature in these transactions is that payment is usually extended over three years; in fact, that canoes are purchased on the three years' hire system. This method of purchase, though but recently adopted by ourselves, has for an unknown period been practised by the naked islanders. The mere fact of its existence demonstrates a high level of commercial morality, for if the debts were often repudiated, the whole system would long ago have collapsed.

This commercial morality corroborates to a considerable extent the ethical standard said to be imparted to the youths during initiation. Nor would I like to say that they acted less up to their standard than we up to ours:

I doubt whether we would be much the gainers by a comparison. In making this statement it must be distinctly understood that I am only comparing their lives with their own ideals, and not judging them by the ethical standards of other races. It is true they were treacherous, often murdered strangers, and were head-hunters; that their ideas of sexual morality differed from ours, but these "crimes" were not prohibited by public conscience, and there was therefore no wrong in their committing them.

Our higher civilization has swept over these poor people like a flood, and denuded them of more than their barbarous customs; the old morality has largely gone too.[1]

FRENCH POLICE PHOTOGRAPHY.

M. ALPHONSE BERTILLON, who has so completely demonstrated the futility of the photograph as a means of judicial identification on any extended scale (see my description of M. Bertillon's system of police anthropometry in the *Fortnightly Review* for March last), when a mere mass of photographs is accumulated with no scientific scheme to aid them, has himself, nevertheless, done more than anyone else to develop and demonstrate the proper subordinate use of the photograph as an agent of the law. M. Bertillon's studies on the subject are not only most valuable to the members of the public administration, but are intensely interesting and instructive to the general reader, and the general scientific student especially, as will be readily acknowledged on a perusal of the young French official's latest publication.[2] He has not only offered me the privilege of making such extracts as I please from this work, but has kindly furnished me with some of the diagrams in the text. This new volume has already attracted considerable attention in France, and will doubtless be received with as much interest in England as have M. Bertillon's previous studies in the domain of anthropology, so that an account of the work in the columns of NATURE seems most opportune.

M. Bertillon begins by describing the sharp distinction between ordinary photography and judicial photography. Artistic and commercial photographs are subordinate to considerations of taste and fashion—not by any means for the purpose of recognizing the subjects of the photographs when met with in after time. The judicial photograph, on the other hand, takes no heed of artistic pose, but must conform to rules which enable the skilled eye to recognize the subject under the most unfavourable circumstances. It relates to various classes of subjects, some known and to be recognized hereafter, such as dangerous criminals; and some unknown and to be, if possible, identified by distant witnesses at the present time, such as suspected persons under arrest, corpses at the Morgue, the wandering insane, lost children, subjects of paralytic shocks, and innumerable human mysteries constantly falling into the hands of the police. The police are thus obliged to be constantly circulating photographs of their own manufacture, and it is of the utmost importance that such photographs should be taken upon the most scientific lines for accomplishing the object in view. Above all, in collecting vast numbers of judicial photographs for future reference—the photographic archives, "cantly" known in English as the "Rogues' Gallery" (though by no means confined to rogues in the eyes of the law)—it is important that the portraits should be taken with uniformity, the questions of full face or profile, full length or bust, &c., being decided beforehand, a fixed scale being adopted. Otherwise two photographs will be often of little use for purposes of comparison.

There is but one object to be attained, and that is easily analyzed—to produce the most perfect likeness, or rather to produce the likeness easiest to recognize, the one most easily identified with the original. The problem in this shape depends on a new factor: Under what circumstances and aspects did those who will be called upon to give an opinion on our photograph know our subject? and leads to this further question: What is the object sought by the judicial inquiry?

If it is a question of taking a sort of print of the individual which, together with his description and judicial record, will enable him to be identified after the lapse of many years, then above all things it is necessary to have recourse to the most lasting features of the human body, and to consult the natural sciences, more especially anthropology. If, on the other hand, it is a question of identification with the past—that is, that our photograph is destined to be compared with others that have been preserved in jails or police offices—the solution is very simple, and consists, above all other considerations, in reproducing the pose, the light, the size, and scale of reduction used in the archives to which our portrait is to be sent.

In regard to the important subject of light M. Bertillon speaks as follows:—"Absolute similarity is unfortunately unattainable. The aspect of the studio, the hour of sitting, the state, more or less cloudy, of the sky, will always betray themselves by the difference in the direction, and the greater or less intensity, of the shadows. We ought first of all to reject, as too complicated, all artistic or fantastic lights. For the full face the light should come principally from the left, a little in front. The pose chair and the apparatus being fixed to the floor at an unchangeable distance, we have for the profile but the direct front or back light to choose from. The light from behind gives more accentuation to the full face, and a more artistic tone. But the interior folds of the ear are necessarily in the shade, and the silhouette does not stand out so clearly as with a front light. The necessity of our profiles being taken with a front light, together with the early hour at which they are taken (so as not to interfere with the magistrates, whose work commences at 12), forces us to take the right profile to the exclusion of the left. In fact, the photograph studios generally facing north, and the sun being south-east between 10 and 11 o'clock, the left profile can only be lighted by a counter light to the camera. In a judicial studio, therefore, thus lighted from the north, the apparatus would be placed on the east sido and the pose chair on the west, the work being done in the morning. By a curious coincidence, and no doubt from analogous causes, the greater number of ethnographic photographs of profile, especially those which compose the superb collection of Prince Roland Bonaparte, are taken from the right side."

The author next discusses the scale to be employed, advocating the necessity of including the shoulders, to show on occasion the crook-backed carpenter, or stiff Briton or Prussian (presumably contrasted with the supple Frenchman), preferring a reduction of 1 in 7 and a distance of 2·56 metres, various technical details being given for the benefit of the artist.

In his second chapter, M. Bertillon takes up the question of the use of the judicial photograph after it is obtained—firstly, as regards identification of two photographs; secondly, identification of a photograph with a person in custody; thirdly, with a person at liberty; lastly (the operation most familiar to the public), identification with a recollection in some one's mind. Of course, it is for this latter object that police portraits are strewn broadcast for the eve of the community at large.

[1] Further information as to customs and legends of the Torres Straits Islanders will be found in the Journal of the Anthropological Institute, vol. xix. 1890, and in *Folk-lore*, vol. i. 1890.

[2] "La Photographie Judiciaire, avec un appendice sur la classification et l'identification anthropométriques." Par Alphonse Bertillon, Chef du Service d'Identification de la Préfecture de Police. (Paris: Gauthier-Villars et fils, 1890.)

But the chief exercise of this function in the ranks of the police themselves is the search among their store of portraits for a person of whom they receive a description, crucial points in this description being set out, and especially the dangers to be avoided. Thus certain colours of hair and complexion make photographs almost unrecognizable, and peculiarities of gesture and movement are so characteristic of some persons as to make mere immobile portraits little suggestive even to familiar acquaintances. As regards comparison between two photographs, the author calls attention to the points which should prevent two apparently dissimilar commercial photographs from being pronounced different subjects; and, on the other hand, the striking family likenesses which should make one careful in declaring two similar portraits the same person. M. Bertillon gives the clue to the physiological data which should govern judgment on these occasions. He illustrates a clever contrivance (but lately borrowed from their French brethren by the English police) by which a newly-taken portrait of a person in custody and an old portrait are compared on equal terms by a covering up of all but the unchangeable portions of the face—hair, beard, and moustaches being obliterated. M. Bertillon makes his most daring speculations, however, in relation to identification of a person at large from a photograph in hand. He says, even as the word "chime" is not conveyed to the brain without a sensation not only of sight of the bells but the sound as well of its ring, so identification should come from certain clue characters of personal appearance, suggesting the absolute identity. It is of no use to sit down and study in detail a photograph which probably tallies in few points with the same person as he is likely to be encountered abroad; but the unchangeable individual data must be seized upon by the trained mind versed in the language of anthropology, so that an encounter with the desired object will never fail to tell the secret. Thus, in the frequent necessity of stopping persons on embarkation at a sea-port, the profile is, of course, the thing to be kept before the inspecting eye; but even this must be understood in relation to the disguise of bearing, expression, &c., all of which must be considered—not the mere photograph taken under far different circumstances. M. Bertillon concludes this interesting section as follows:—"The officer charged with so difficult a mission as the search for, and arrest of, a criminal by the aid of a photograph, should be able to repeat and write from memory the description of the face of the man he is in search of. It is the best means of proving to his chiefs that he has at heart the task confided to him. The reader will see later the special terminology which a knowledge of the subject necessitates. More than one of our readers will be surprised to see that police science borrows some of its methods from natural history and mathematics. We think that this descriptive study of the human frame will interest the portrait photographer as much as it will the judicial inquirer. Are not both scrutinizers of the human physiognomy, though truly from a different point of view?"

The author's third chapter is devoted to other applications of photography to judicial purposes. Here he refers to the notorious pocket cameras, which he puts aside as rarely of much use for police purposes, it being at a critical moment more of an object to capture a malefactor than to photograph him. Still, he admits an occasional value for this kind of photography, and gives a startling example of the scene of a most dramatic murder in the suburbs of Paris at the instant of its discovery, before anything of the surroundings had been disturbed. This, M. Bertillon contends, would naturally be most valuable in the hands of the prosecution. Numerous other uses of photography are mentioned, such as cases of mine accidents, traces in the snow before it melts, and other matters of future judicial investigation. Many objects connected with crime may become the subject of photography, such as weapons and portions of dress; and photochromography comes in opportunely to spread abroad not only the form but the colour of the articles considered important in tracing a criminal, so that evidence as to such articles may be forthcoming.

In his appendix, M. Bertillon gives an interesting summary analysis of the human figure, based on the studies of Quételet; but as this is only indirectly connected with the subject in hand, I will only refer to the two features on the importance of which in judicial investigation the author lays the greatest emphasis—namely, the nose and the ear. That important and delicate subject over which so much concern is evinced in the social circle and the domain of literature—the human nose—M. Bertillon considers equally worthy of prominence in anatomical study and police practice. He offers a scheme whereby noses may be studied with profit to the judicial mind, discarding the considerations which chiefly appeal to the ordinary eye in comparisons—colour, size, and general shape—and confining the classification to the line profile pure and simple, apart from all other elements. M. Bertillon makes fifteen classes, into which all noses, even the most eccentric probosces, may be sorted: firstly, three grand divisions—the *elevated*, the *horizontal*, and the *drooping*, according to the nature of the base-line; each of these to be again divided by the bridge line into *concave*, *straight*, *convex* (or curved), and, lastly, *undulating* (wavy, broken, or irregular in outline). The detective or judicial functionary, when called upon to say whether a face under his surveillance corresponds with a photograph in question, will find great help in a thorough nasal analysis, for two noses are never exactly alike.

Yet more important is the ear, which, M. Bertillon insists, should always be shown in the portrait. His remarks on this feature are so valuable that I will conclude my summary of his unique little volume by an abstract from this portion, illustrated by the accompanying diagrams, the use of which has been so kindly allowed me by the author:—

"We will close our examination of the profile by studying the ear, which, thanks to the projections and depressions with which it abounds, is the most important factor in the problem of identification. It is all but impossible to find two ears identically similar in all their parts, and the variations in the conformation which this organ presents appear to remain without modification from birth until death. We believe that the registration at birth of certain peculiarities in the ear would render any substitution of persons, even when adults, impossible. From birth unchangeable in its form, uninfluenced by surroundings or education, this organ remains throughout life like the untangible legacy of heredity and interuterine life. Nevertheless, on account of its immobility itself, which prevents its taking any part in the play of features, no part of the face less attracts the attention of the profane. Our eye is as little accustomed to notice it as our tongue is to describe it. In fact, the denominations of the principal parts of which it is composed have been but very summarily described in most of the anatomical treatises.

"It will be sufficient for us to confine ourselves to the prominences which border the depressions, to give a good idea of the latter, and it will enable us to shorten our description by one-half. The prominences are five in number.

"(1) The border of the ear, or helix, a semicircular projection commencing at A (Fig. 1) in the middle of the ear, above the auditory passage, reaching to the periphery, and bordering two-thirds of the upper ear.

"(2) Where it ceases, the lobe commences soft and rounded, terminating at the base the circumference of the ear.

"(3) Then the tragus—small, flat, triangular, cartilaginous prominence—placed outside in front of the auditory

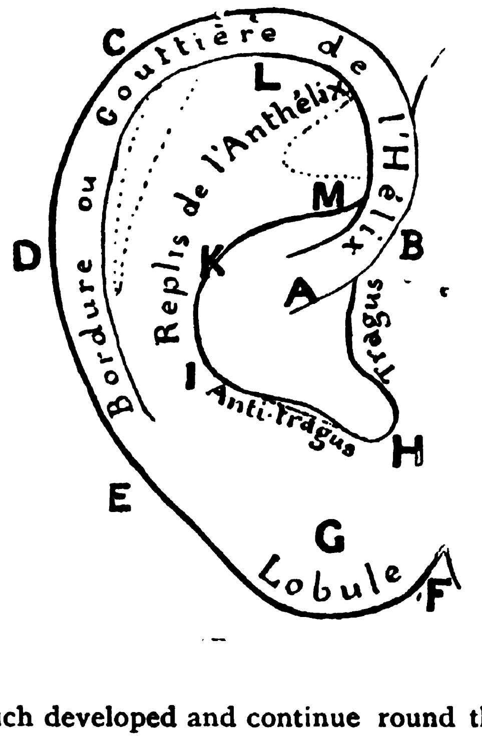
passage. Its shape presents but few individual variations.

"(4) Opposite, separated by the auditory passage, is the antitragus, less prominent than the tragus, but of far greater descriptive value.

"(5) Finally, above it the fold of the anthelix, which, after rising about 1 centimetre, bifurcates in two branches, the upper and the horizontal, the latter rejoining the helix above its original starting-point.

"The above order of enumeration enables us to draw the different contours of the ear without raising our pencil, starting from point A, and finishing at point M; this course of the pencil is shown on Fig. 1 by the alphabetical order of the capital letters, which separate each of the subdivisions, of which we are about to describe the most characteristic morphologic variations.

"The border may be divided into four parts—the starting-point, A B; the anti-superior part, B C; the posterior, C D; and the final, D E. Each of these parts may vary independently—that is to say, may be small, medium, or large. It also happens pretty frequently that the beginning and ending portions (A B or D E) are altogether missing; at other times the portion C D is more fully developed than the superior or upper part, or less so. The irregularities of contour that result therefrom are very characteristic. Lastly, the final part, D E, may



be very much developed and continue round the lobe to the cheek.

"The *lobe* should be considered—

"(*a*) The outline of its free edge, E F, which may terminate in a descending point, and attached to the cheek, or squared, or in rounded ellipsoid.

(*b*) "Its degree of adherence to the cheek, F H, which we called 'fused,' or it may be joined by a membranous fold, which only becomes visible when the ear is stretched from the cheek. Finally, it may be entirely separated from the cheek.

"(*c*) Of the shape of the anti-exterior surface, G, which may be traversed by the prolongation of the helix, level or mammilated.

"(*d*) Of its dimensions in height, which may be small, medium, or large.

"The *antitragus* presents a general line of direction, the inclination of which may vary from horizontal (the head being in its normal position) to obliquity of 45°. In relation to this line, represented in the drawing by the dotted line H I, the antitragus can profile in line with an upper concavity, or rectilinearly, or slightly sinuous, or projecting. Finally, the antitragus (especially its free extremity) may be inverted outwards or straight. Putting aside all questions of shape, the antitragus may vary also with reference to its indefinite dimensions.

"The parts I K and K L of the fold of the *anthelix* may each separately be small, medium, or large. When the anthelix, and specially the upper branch, K L, is little accentuated, the ear stands out from the head, and takes a shape which resembles the ear of the mammifer. The horizontal portion, K M, of the anthelix has a bearing sometimes truly horizontal, sometimes oblique, sometimes intermediate.

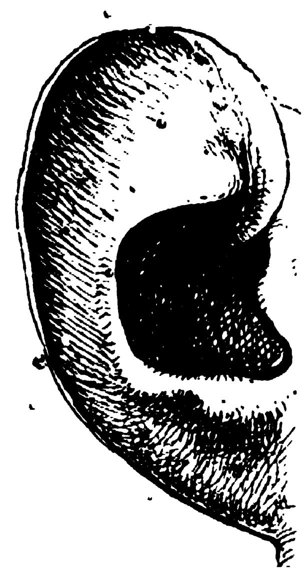


Fig. 2.—Ear showing all the characteristics at a minimum.

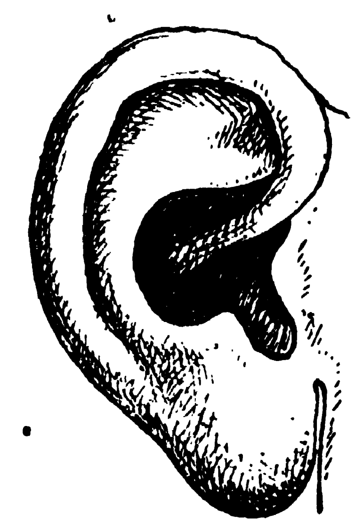

Fig. 3.—Ear showing all the characteristics at a maximum.

Fig. 4.

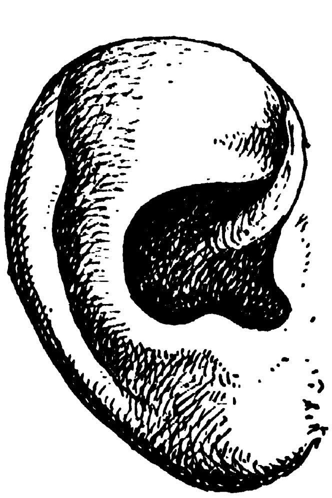

Fig. 5.

Figs. 4 and 5.—Ears showing the corresponding peculiarities alternately at a minimum and at a maximum.

"The whole ear, including the lobe, may equally deflect from the head; hence the shape called "peduncular" by some authors. In other cases the deflection is most noticeable in the posterior part, or upper, or even in the lower part of the ear. We must also notice the presence of a prominence in a certain number of ears, between the points C and D. This protuberance is called 'the tubercle of Darwin,' after the celebrated English naturalist, who saw in it a survival of the pointed ear of certain monkeys (Fig. 5)."

It is to be hoped that M. Bertillon's work will be seen in English, for I have given but a fragment of the choice, fresh matter in the little volume.

Edmund R. Spearman.

THE CINQUEMANI "CHRONOLOGE."

THIS is a very singular and interesting contrivance. It is a clock with only one toothed wheel, yet it shows the hours, minutes, days of the week, &c., and strikes the hours and quarters at each quarter of an hour. Moreover, there is an arrangement for repeating the hours and quarters at will. The single toothed wheel spoken of is the escape-wheel, and this propels a pair of pallets and pendulum in the ordinary way. The rest of the work is done in the fall of a small leaden ball, a long chain of these balls being intermittingly elevated, and one of them discharged over a revolving drum each quarter of an hour. We will follow one of these balls through the course of its multifarious duties. It first enters a sling in a tape wound over the escape-wheel axle, and we notice that it is the weight of this and three other balls (which have been previously deposited in preceding slings) which is keeping the escape-wheel going. As the wheel turns round, the balls descend, and after a quarter of an hour the lowest will have arrived at a funnel-shaped opening, where it will get liberated from its sling, and fall. It first strikes a lever which enables the drum to move on and discharge another ball into a sling upon the escape-wheel tape. Then rushing down a tube it enters a zigzag. It is within this zigzag that the striking of the quarters is performed, for at each of its angles a bell is placed, against which the ball strikes sharply as it passes them. After leaving this zigzag, the ball is projected down another, where it strikes the hours. As the number of blows to be struck is regulated by a similar contrivance at each zigzag, we will confine our attention to that for the hours. The channel down which the ball passes is vertical to the face of the zigzag. Now the front or zigzag side of this channel is a moving tape, which carries a little trap. As the tape is always moving, the position of the trap depends upon the time, and the position of the trap also determines the stage of the zigzag upon which the ball will be projected. Thus, when the trap is opposite the sixth stage of the zigzag, the ball will encounter six corners upon its way down, and consequently six blows will be sounded. When the trap is at the top, twelve blows are sounded; and when the trap is at the bottom, no blows are sounded. When the ball leaves the zigzag, it enters a sling at the lowest part of the chain first spoken of, and is intermittingly carried up again to begin its work over again. For repeating the hours and quarters at will, there is a separate reservoir of smaller balls; and by pulling a handle one of these can be discharged above the first zigzag, and when it has done its work it disappears through a hole, which the regular balls cannot penetrate, back to its own reservoir. It may be mentioned that, in lieu of bells, the hour zigzag has a single vertical sonorous tube for each set of corners. The time, days of the week, &c., are shown by means of tapes carrying pointers suspended over the escape-wheel and another axle. The inventor, the Rev. Canon Cinquemani, maintains that the simplicity and precision, by reason of the constant force on the escapement of his "chronologe" (which he has patented), render it peculiarly advantageous for missionary and other distant stations, where the assistance of professional clockmakers is not readily procurable. H. D. G.

THE NEW AUSTRALIAN MAMMAL.

IN vol. xxxviii. of NATURE (p. 588), Dr. E. C. Stirling, of Adelaide University, described as a "new Australian mammal" a small mole-like animal which had been obtained in Central Australia near the telegraph line between Adelaide and Port Darwin. The same description, with some additions, was afterwards published in the Transactions and Proceedings of the Royal Society of South Australia, vol. x. p. 21. But no decision was arrived at as to the exact affinities of this animal—not even whether it is a Marsupial or a Monotreme—nor has any name been given to it. On behalf of the zoologists of this country, who have waited patiently two years for further information, I now venture to urge Dr. Stirling to send one of his specimens of this extraordinary creature (in a letter subsequently addressed to me he speaks of having received two additional examples) to London, and allow us to endeavour to decide what it really is. I need not point out the extraordinary interest of this discovery. If a Monotreme, as seems probable, it will be the third known form of this very peculiar type of mammal-life; if a Marsupial, it is quite different from all known members of that group; and if it turns out to be a Placental Mammal, it will revolutionize our canons of zoological geography. On behalf of the Zoological Society of London, I think I may promise that the specimen, if forwarded, shall be submitted for examination to our very best authorities on the subject, and shall be fully described and illustrated in our scientific publications. Such a grand discovery should certainly not be concealed from the world's knowledge any longer.

P. L. SCLATER.

RICHARD BURTON.

WE have already announced the not unexpected death, at the age of 69, of Sir Richard Burton, one of the most versatile geniuses and extensive explorers of any time, and one who, so far as Africa is concerned, deserves to be ranked with Stanley and Livingstone. He was born on March 19, 1821, at Barham House, Herts, of old families on both sides, and with a heritage of fighting and wandering propensities. It is curious now to think that Burton was sent to Oxford with a view to taking orders. He soon destroyed all prospects of any such career by getting himself rusticated. He succeeded in obtaining an appointment in an Indian regiment, and, while yet little more than a boy, his restless wanderings began. For half a century Burton lived a life of the fiercest intensity—equal to the lives of three ordinary men. Before his famous journey to Mecca he had published more than one book on his travels in India and neighbouring countries. Before attempting the hazardous enterprise to the holy city of the Moslems, in 1852, he took every precaution to delude his fellow-pilgrims into the belief that he was one of the faithful. His extraordinary gift of picking up languages made this easy; and whether his disguise was or was not penetrated, he succeeded in getting inside, and, better still, outside Mecca, to tell an expectant world of mysteries practically unrevealed before. This journey would certainly have made his name famous; but he meant to do even greater things. At that time it was as dangerous to attempt to enter fanatical Harrar as it was for a Christian to join the Haj. But Burton did it, and lived to tell the world the story of it; though he and Speke had a narrow escape when, the following year (1855), they attempted to reach the Nile through the Somali country.

A preliminary trip to Zanzibar produced a learned and interesting book on that island and its people. We say preliminary, because by this time, 1856, Burton had something much more important in view. Livingstone, it should be remembered, had been at work in Africa for many years; in 1856 he returned to England to tell the full story of his crossing of the continent. Through Livingstone, through Krapf and Rebmann, and others, rumours had been for a long time coming out of great lakes in the interior. Before D'Anville, in the end of last century, made a clean sweep of all the crowded features on the map of Central Africa which had accumulated since the end of the sixteenth century, there were lakes in plenty, scattered over the centre of the continent, and great rivers and mountain ranges, some of them an inheritance from the days of Ptolemy. But no one knew how these features ever came there. The hydrography they in-

dicated was impossible; and there was no evidence that any white traveller had ever seen them. The probability is that these lakes and rivers were put down from the reports of natives who had communications with the interior. Much of the existing geography of Africa rests on no better foundation; but then we know better how to sift native reports now than our predecessors did 200 years ago. At all events, as some of us who were at school then may remember, the map of Africa, in 1856, had the word "Unexplored" spread all over its centre. As has been said, Krapf and Rebmann, the missionaries, who had seen Kilimanjaro, and thought they got a glimpse of Mount Kenia afar off, had heard of great lakes in the heart of Africa. It was to seek these lakes that Burton, accompanied by Captain Speke, set out from Zanzibar in June 1857. The expedition was under the auspices of the Government and of the Royal Geographical Society. Before leaving Zanzibar Burton wrote home that he was about to set out in search of "the Great Lake." His eyes were gladdened by the sight of the waters of Tanganyika, at Ujiji, on February 14, 1858. It is scarcely possible for us to realize what this meant at the time. The route, now so well known, from Zanzibar to Ujiji had never before been trodden by the feet of white men. The difficulties which beset this pioneer expedition were disheartening. Before it set out, there was no Tanganyika, no Victoria Nyanza, no Albert Nyanza, no Bangweolo on the map, and only the lower 200 miles of the Congo. Burton's discovery of Lake Tanganyika may be regarded as the centre from which all succeeding discoveries in Central Africa have radiated. It is the great central lake round which all others are grouped. Indeed Burton's companion, Speke, as we know, made a run to the north on the homeward route, and discovered that other great lake, the Victoria Nyanza, which he rightly surmised to be the source of the White Nile. Of the unhappy relations between Burton and Speke this is not the place to write, even if we had any inclination to revive a bitter controversy that ought to be allowed to lie in the grave where it was placed many years ago. That Burton's bitterness against Speke blinded him to the importance of his companion's discovery all will admit. That Burton was of a rough type, given, like other great and successful men, to carrying out his purposes at any cost to themselves and others, there can be no doubt. The big things in the world have generally been accomplished by such men.

Burton's discovery gained him the medal of the Royal Geographical Society, but hardly anything else. After a run to America, he, in 1861, with his newly-married wife, went as Consul to the White Man's Grave—Fernando Po. From here he explored the Cameroons, the Gorilla country, and Dahomey. A few years later a Consulate in Brazil gave him the opportunity of exploring the highlands of that country. After a short stay at Damascus, Burton was appointed Consul at Trieste in 1872, and there he was allowed to vegetate till his death, with no greater reward for all his valuable services to science than a K.C.M.G., given him four years ago. Visits to Iceland, to Midian, and to the Gold Coast, produced several volumes to add to the many he had already published; probably no traveller has ever been so prolific in books. It says little for the intelligence and enterprise of a Government that could find no better use for the services of a man of such power as Richard Burton than to give him the charge of a third-rate Consulate. Of Burton's versatile scholarship and its published results we need not speak in detail. He was one of the few survivors of the old type of adventurer of which our country has been so prolific—men who have been the makers of our Empire and the founders of modern knowledge. Science is bound to remember him as one of her pioneers into the great unknown. K.

PROFESSOR HEINRICH WILL.

THE sad announcement of the death of this well-known chemist from heart disease, on the 15th of this month, is made in the *Chemiker Zeitung* of the 22nd inst. Dr. Will was for thirty years Professor of Chemistry and Director of the Laboratories at the University of Giessen. He was born on December 8 in the memorable year 1812, at Weinheim, where his father held an important official position. After completing his studies at the High School of his native town, he devoted himself for a time to pharmacy. But in 1834 he entered the University of Heidelberg, and in the same year undertook the position of assistant in the laboratory under Prof. Geiger, and after that eminent chemist's decease, in 1836, under the celebrated Prof. L. Gmelin. In 1837, at the request of Prof. von Liebig, he removed to Giessen, where he occupied the position of assistant until his graduation as Doctor in 1839. He then habilitated himself at the University as Privat-docent of Chemistry, his dissertation consisting of a description of his "Investigation of the Constitution of the Ethereal Oil of Black Mustard." In 1842, Dr. Will undertook the direction of the newly-founded Filialslaboratorium, and in 1846 he received a call to the then recently inaugurated laboratory of the College of Chemistry in London. He, however, declined the offer, and was shortly afterwards appointed extraordinary Professor in the University of Giessen. After Prof. von Liebig's departure for Munich, in 1852, Dr. Will became ordinary Professor of Chemistry and Director of the Chemical Laboratories of the University. During the session 1869-70, Prof. Will occupied the distinguished post of Rector of the University, and his inaugural address was a memorable one, treating of the relations between matter and force considered from the chemical standpoint. After forty years' unceasing labour as a teacher and an investigator he retired, at his own request, in October 1882.

As an original investigator Prof. Will was characterized by his precision and the acuteness of his observation. He was also a most excellent teacher, understanding as few others of his time the art of explaining to students that which was so clear to himself. What, however, most struck those who had the good fortune to listen to his lectures, was the deep earnestness which he threw into his subject, and the manner in which he used to carry his students along with him through the most intricate branches of chemistry. His powerfully energetic character was even more apparent if possible in the laboratory, as he passed from student to student, speaking the right word of help and encouragement to each, and inculcating habits of work and thought which raised many of those students to positions of honour and usefulness in the chemical world. His especial fitness for the leadership of a laboratory is very manifest from a perusal of his text-book, "Anleitung zur chemischen Analyse," which appeared in its twelfth edition in 1883, and has been translated into several languages. A. E. T.

NOTES.

THE Queen has been pleased to command that the Government institution now known as the Normal School of Science and Royal School of Mines shall in future be called the Royal College of Science, London.

THE President of the Institution of Electrical Engineers and Mrs. John Hopkinson will give a *conversazione* in the galleries of the Royal Institute of Painters in Water Colours on Wednesday evening, November 19.

THE death of Robert M'Cormick, F.R.C.S., R.N., Deputy Inspector-General of Hospitals and Fleets, is announced. He was one of the oldest and most eminent officers of the medical

profession in the Royal Navy. He accompanied Sir E. Parry in H.M.S. *Hecla* in his attempt to reach the North Pole, and in 1839 joined the *Erebus*, which, in company with the *Terror*, was employed in the expedition for magnetic observation and discovery in the South Polar regions. During this voyage, which lasted four years, he discharged, in addition to his medical work, the duties of geologist and zoologist. In 1847 he called the attention of the Admiralty to the fate of Sir John Franklin, and laid before the Board plans of search for the missing vessels. His plans were accepted in 1852, and in the course of his subsequent exploration he settled various geographical questions. In 1857 he received the Arctic medal. Among his writings are: "Geology of Tasmania, New Zealand, Antarctic Continent, and Isles of the South," "Voyages of Discovery in the Arctic and Antarctic Seas," and "Round the World, with an Open Boat Expedition, in the *Forlorn Hope*, in Search of Franklin."

WE have to record the death of Mr. E. C. Nicholson, F.C.S., who was well known as a manufacturing chemist. He died on the 23rd inst., at the age of sixty-three.

A SCIENTIFIC and commercial expedition to the West Coast of Africa, under the auspices of the British Government, is about to leave London. Commander V. Lovett Cameron has been appointed chief of the staff, the whole expedition being under the superintendence of Mr. James Bennett, of the firm of E. C. Bennett and Co.

STUDENTS of Egyptian Archæology will be glad to learn that the Catalogue of the Gizeh Museum will be published in January.

THERE have been some unpleasant rumours lately about the destruction of the Pyramids for building material. The Cairo correspondent of the *Times* says there is no truth in these reports. The real facts are that the loose stones accumulated at the base are being removed, which will lay bare the lowest courses and display the Pyramids to greater advantage. The work is being conducted under the superintendence of the Museum authorities.

THE botanical explorer, Mr. C. C. Pringle, was engaged, during the early part of this year, in investigating the high land between Mexico and Tarupico; he has made large collections, including, as he believes, many new species.

DR. R. VON WETTSTEIN returned in July from his botanical expedition to Tuzla, Zwornik, Vlasenica, and Srebrenica in Eastern Bosnia. He has obtained interesting results, which will be published in the *Oesterreichische botanische Zeitschrift*.

ON October 16, Prof. Wallace delivered the inaugural address to the class of agriculture and rural economy at the Heriot-Watt College, Edinburgh. He chose as his subject dairy practice. The address has now been published.

THE October number of the *Auk*, which completes the seventh volume of that publication, is a somewhat bulky part, and besides the usual excellent papers on North American ornithology, it contains some essays by European naturalists. Dr. A. B. Meyer describes a new species of Humming Bird (*Eriocnemis aurea*) from Colombia. Mr. Eagle Clark gives an account of a collection of birds made by Dr. Gillespie at Fort Churchill, Hudson's Bay, and presented to the Edinburgh Museum in 1845. Mr. J. A. Allen describes a new *Icterus* from Andros Island in the Bahamas, as *Icterus northropi*. Mr. D. G. Elliot also publishes the first portion of his description of a collection of birds obtained by Mr. C. F. Adams at Sandakan in North-Eastern Borneo. This paper contains many errors, and the author is evidently not acquainted with the recent literature on the subject. *Copsychus adamsi*, sp. n., is certainly *C. niger* of Wardlaw Ramsay (P.Z.S., 1886, p. 123). Mr. Seebohm, not Mr. Sharpe, is the author of the fifth volume of the "Catalogue of Birds," and he will probably be interested in the occurrence of *Geocichla interpres* in Borneo, which is here recorded for the first time. *Pitta venusta* of Mr. Elliot's paper will assuredly prove to be *Pitta nosheri*, already recorded from Sandakan, by Mr. Bowdler Sharpe, in the Proceedings of the Zoological Society for 1881, a paper which seems to have escaped Mr. Elliot's notice. He will also find Mr. Alfred Everett's "List of the Birds of Borneo" of great use to him in his future studies.

THE authorities of the Government Central Museum, Madras, are having an index collection made on the same principle as that adopted in the British Museum (Natural History). This is noted in the Administration Report of the Museum for the year 1889–90. The index collection, in its complete state, should teach the most important points in the structure of the principal types of animal and plant life, and the terms used in describing them. The series exhibited during the past year illustrated, by means of specimens with descriptive labels, arranged in wall and table cases, the outer covering or integument of mammals and its modification into hair, nails, claws, hoofs, horns, antlers, &c. Other series are in course of preparation, illustrating the dentition and osteology of mammals, the external characters and osteology of birds, the structure and forms of shells, mimicry, &c. The exhibition of these series, the Superintendent hopes, will be of use both to those who are engaged in teaching, and to students in Madras, and bring the Museum more into touch with the Educational Department than it has been hitherto.

SOUNDINGS have lately been carried on in the Straits of Dover, in connection with the proposal for the construction of a bridge across the English Channel. According to a telegram sent through Reuter's Agency from Paris, the result of the surveys made shows that the route which has been investigated is a little shorter than was expected, that it presents every guarantee as regards solidity and stability, and that the depths are not quite so great as was anticipated. M. Renaud, a hydrographic engineer, who was designated for the work by the French Minister of Marine, is of opinion that if the Bridge Company went a little further north a perfectly straight route could be obtained with a better foundation and less depth of water. This route would be four kilometres shorter, and would therefore considerably decrease the cost of construction. It also appears to be less exposed to the wind, which would prove a great advantage, especially during the progress of the works.

THE U.S. National Museum has issued its Thirty-eighth Bulletin. The work consists of a valuable contribution, by Prof. J. B. Smith, towards a monograph of the insects of the Lepidopterous family Noctuidæ, of Temperate North America.

SOME time ago a memorial on the decimal system was presented to the London School Board by the Decimal Association. The Board have now informed the Association that, on the recommendation of the School Management Committee, they have asked the Education Department to modify Schedule I of the new Code, so that decimal fractions shall be taught in the fourth standard at latest, and the metric system of measurement and weight be included in the teaching of the fourth and upper standards. The School Management Committee of the Board have also decided that models illustrating the metric system shall be added to the Board's requisition list in the event of the Education Department accepting the proposal of the Board.

MESSRS. J. B. BAILLIÈRE ET FILS are issuing, in weekly parts, a work on the various races of mankind ("Les Races Humaines"), by Dr. R. Verneau. It will complete the work entitled "Merveilles de la Nature," for which Brehm wrote the

"Vie des Animaux." The first part of the new work has been sent to us. The author arranges his facts clearly, and there are some good illustrations.

MR. FISHER UNWIN has published an interesting volume on "Teneriffe," by George W. Strettell. It is an expansion of a paper read by the author before the Congress at Brighton last August. Mr. Strettell records his personal experiences, and in describing Teneriffe as a health resort, avoids, with equal care, extravagant laudation on the one hand, and undue depreciation on the other.

THE new volume of the "Minerva Library" consists of reprints of Darwin's "Structure and Distribution of Coral Reefs"; his "Volcanic Islands"; and his "Geological Observations on South America." Prof. J. W. Judd contributes a critical introduction to each work.

A CORRESPONDENT inquires as to the titles of any works in the nature of scientific guide-books to Switzerland and the neighbouring countries, and to the usual tourist resorts for health, &c.—which deal with their chief features of botany, zoology, geology, ethnology, &c. The books should not exceed the size or cost of ordinary guide-books, and may be French or English. We shall be glad to print any titles that may be sent to us.

A SOMEWHAT severe shock of earthquake occurred at Hechingen on October 14, at 2.30 a.m. At Nexö, on the Island of Bornholm, a slight rumbling of earthquake was noticeable for almost an hour on October 8, the same day on which several shocks were felt in Norway.

THE formation of icebergs was watched, this last summer, by Mr. H. B. Loomis and Prof. Muir, while staying seven weeks near the Muir Glacier (*Amer. Journ. of Science*). The falling of blocks from the terminal wall was very irregular; at times, about every five minutes; while at other times the observer might wait an hour without seeing one fall. One day, in twelve hours, 129 thundering reports from the falling bergs were heard at camp, about a mile off. In heavy rain, especially, it seemed as if a thunderstorm or cannonade were going on. Sometimes a block, breaking off, bursts into fragments, and falls like a cataract. Again, an enormous block will sink unbroken into the water, then rise, perhaps 250 feet, even with the top of the glacier, the water pouring off it; then topple on its side with a heavy thundering roar, scattering spray in all directions, and wallow about among other icebergs like a huge monster.

A PAMPHLET on "The Law of Storms," considered with special reference to the North Atlantic, has been sent to us by the author, Mr. Everett Hayden. It is an abstract of a paper read by him before the National Geographic Society in November last. Hurricanes are most frequent in the summer months in each hemisphere. Originating in the tropics they move westward, then poleward, and finally eastward in higher latitudes, gradually receding from the equator. Between hurricanes north and south of the line the essential difference is that in the northern hemisphere the rotation of the cyclonic whirl is against the hands of a watch and in the southern with them. The author goes on to say that the noted hurricane regions are the West Indies, coast of China and Japan, Bay of Bengal (especially in May and October at the time of the change of the monsoons), and the South Indian Ocean (about Mauritius). In the brief statements and descriptions regarding hurricanes and storms, including some of the latest hurricanes that have occurred in the last two or three years, the most recent, most important, and best established facts, which every navigator ought to know, have been written concisely and intelligibly. Accompanying these descriptions are charts which illustrate clearly the wind currents and barometric depressions. To explain the great cloud bank, and the storm wave or general elevation of the sea caused by the spirally in-blowing winds and low barometer, the author has given a very neat little sketch in cross-section, and a second sketch is added to convey a clear mental conception of the actual motions of the particles of air as they flow inwards from below, their whirl upwards and flow outwards at the top.

IN a paper on moles, lately read before the Bristol Naturalists' Society, and now printed in its Proceedings, Mr. C. I. Trusted calls attention to the fact that there are said to be no moles in Ireland. He has never seen a mole-hill in that country, and an acquaintance of his at Belfast—"a good and observant naturalist"—says, "It *is* a fact that moles do not exist in Ireland." Yet, as Mr. Trusted points out, there are in many parts of Ireland wide districts which seem to be well suited to the mole's habits.

THE Department of Public Instruction, in New South Wales, have printed in their technical education series a valuable paper on wattles and wattle-barks, by J. H. Maiden. In an introductory note the Minister for Public Instruction says that experiments in wattle-culture in Victoria and South Australia have resulted in a practical success. He knows of no sound reason why similar enterprise should not be equally profitable in New South Wales, which has, in many parts, soil and climate well adapted for this industry.

SOME persons digging peat near the village of Fochterloo, Friesland, lately came across a sunken forest of trees with enormous trunks. The trees are lying on a sandy soil, in the direction from north-west to south-east; it is not yet decided to what species they belong. The exteriors resemble oak, but the insides are brittle, and burn like tinder.

WE have received the third edition, just published, of a general list of observatories, astronomers, astronomical societies, and astronomical reviews, prepared by Mr. A. Lancaster, librarian of the Royal Observatory of Brussels. Under the heading of each observatory will be found its latitude and longitude, the names of all those who compose its staff, and its yearly publications. Under astronomical societies the information given relates to the following: date of foundation, object, memoirs published, and names of the president, secretary, and treasurer. The next part is headed, "Institutions diverses," and includes—among other institutions—the Bureau of Longitudes of France at Paris, Bureau of the *Nautical Almanac* at London, Bureau of the *Nautical Almanac* at Washington, Solar Physics Committee, &c. The staff employed or members in each of these institutions is given, together with the yearly publications. The fourth section deals with astronomical reviews and journals, and the information that is brought together mentions the name of the editor, the price, the frequency of publication, and the date of first appearance. The fifth and sixth sections consist of alphabetical lists, with addresses, of astronomers and instrument makers. With the help of the good general alphabetical table that is added at the end, the book will be sure to be found very handy and useful for reference.

R. FRIEDLÄNDER AND SON, Berlin N.W., 11 Carlstrasse, have issued part xxiii. of their "Catalogues of Books." It contains titles of a large number of important works dealing with every branch of astronomical science, hence it will be of great use to those in search of rare books, and also to the general bibliographer.

WE have received the sixth fascicule of the "Works of the Aral-Caspian Expedition," which contains the geological diary of Prof. Barbot de Marny during the Expedition. This diary, which unhappily remained unpublished for thirteen years after the Professor's death, is rich in accurate observations, which

have lost none of their value, notwithstanding subsequent exploration; and the whole gives a vivid description of the explored region, from the Caspian Sea, over the Ust-Urt plateau, to the mouth of the Amu-daria and to Samarkand. Of the many short notes scattered in the diary we may select one in which it is mentioned that Barbot de Marny has had the opportunity of finally ascertaining that the so-called *bugry* of the Caspian shore are simply due to denudation. The layers of clay and sand of which they consist are mostly horizontal, and, when they are not so, the stratification has no relation whatever to the exterior shape of these elongated low ridges. The next contribution to the same fascicule is by M. Andrusoff. It is full of geological data, and its conclusions are very interesting, the author never failing to discriminate between what is already proved and what still belongs to the domain of hypothesis. His remarks about the Caspian Sea and its present fauna being remains of a Miocene sea, and the enumeration of the geological problems in connection with that fact which remain yet unsettled, will be read by geologists with interest, the more so as the substance of this paper has been given in German in the *Jahrbuch der k.k. Geologischen Reichsanstalt*, vol. xxxviii.

THE following are the arrangements for Tuesday evening lectures at the Royal Victoria Hall during November:—November 4, Mr. Arnold Mitchell, "Old Buildings and the Story they tell"; November 11, Mr. A. H. Gilkes, "Columbus"; November 18, Mr. A. P. Laurie, "Air and Water," with experiments; November 25, Mr. Hilliard Atteridge, "The New Divisions of Africa." The oxyhydrogen lantern will be used with all these lectures.

IN our note on the Rev. J. A. Galbraith, on October 23, the last three lines should have been printed as follows:—"In 1854 he was chosen Erasmus Smith Professor of Experimental Philosophy. Along with Dr. Haughton, Prof. Galbraith was the author of various excellent scientific manuals."

IN a communication to the current number of the *Comptes rendus*, M. Moissan announces the result of his redetermination of the atomic weight of fluorine. The method adopted consisted in converting a known weight of sodium, calcium, or barium fluoride, prepared in a manner specially devised by M. Moissan in order to exclude impurities, into sulphate by repeated ignition with pure sulphuric acid in a small platinum retort. The process for obtaining pure sodium fluoride was as follows. An already fairly pure specimen of sodium chloride was freed from the last traces of potassium by a large number of fractional crystallizations. This was then converted into bicarbonate, of soda by saturating its aqueous solution successively with ammonium and carbon dioxide. The precipitated bicarbonate, after repeated washing, was converted into the normal carbonate by boiling its solution in water, and the crystals which separated on evaporation were freed from traces of chloride by repeated partial crystallization. The carbonate was next converted into fluoride by treatment with redistilled hydrofluoric acid originally prepared by distillation of hydrogen potassium fluoride, HF . KF. The sodium fluoride thus obtained, after ignition at a red heat, was probably the purest specimen which has ever been obtained. As the result of five ignitions with sulphuric acid, the values obtained for the atomic weight of fluorine ranged from 19·04 to 19·08, when Na = 23·05 (Stas), S = 32·07 (Stas), and O = 16. The calcium and barium fluorides employed in the second and third series of determinations were obtained in microscopic crystals by precipitating potassium fluoride with calcium or barium chloride in dilute solutions of particular strengths. The values obtained in the case of four experiments with calcium fluoride varied from 19·02 to 19·08, and as the result of five determinations with barium fluoride, 19·05–19·09. As barium fluoride is not so regularly decomposed by sulphuric acid as sodium and calcium fluorides, M. Moissan considers that the nearest approximation to the truth is afforded by taking the mean of the experiments with the the two latter fluorides. This value is 19·05. Hence the atomic weight of fluorine may be considered, as has previously been supposed, to be practically represented by the whole number 19.

THE additions to the Zoological Society's Gardens during the past week include a Diana Monkey (*Cercopithecus diana* ♀) from West Africa, presented by Mr. Howard V. Henry; a Spotted Ichneumon (*Herpestes nepalensis*) from Nepal, presented by Mr. J. Percy Leith, F.Z.S.; a Polecat (*Mustela putorius*), British, presented by Mr. F. D. Lea Smith; two Laughing Kingfishers (*Dacelo gigantea*) from Australia, presented by Mr. W. B. Phillips; two Pomatorhine Skuas (*Stercorarius pomatorhinus*), British, presented by Mr. T. E. Gunn; a Cashmere Monkey (*Macacus pelops* ♀) from Cashmere, deposited; two Common Squirrels (*Sciurus vulgaris*), two Reed Buntings (*Emberiza schœniclus*), two Redpolls (*Linota rufescens*), British, purchased; an Angora Goat (*Capra hircus* ♀ var.), received in exchange; two Vinaceous Turtle Doves (*Turtur vinaceus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on October 30 = 0h. 36m. 39s.

Remarks.

(1) The spectrum of this bright nebula has not yet been recorded. The G.C. description is: "Very bright; very large; much extended in the direction 165°; very gradually very much brighter in the middle."

(2) This is the companion to the Great Nebula in Andromeda, which is described by Herschel as "exceptionally bright; large; round; pretty suddenly much brighter in the middle to a nucleus." With reference to the spectrum, Dr. Huggins notes: "This small but very bright companion of the Great Nebula of Andromeda presents a spectrum exactly similar to that of 31 M (the Great Nebula). The spectrum appears to end abruptly in the orange, and throughout its length is not uniform, but is evidently crossed either by lines of absorption or by bright lines." Referring to the Great Nebula, the same observer wrote: "The spectrum could be traced from about D to F. The light appeared to cease very abruptly in the orange; . . . no indications of the bright lines." A comparison of the two descriptions would lead one to suppose that the spectrum of the companion is the more discontinuous of the two, and, if this be the case, measurements of the positions of the brightnesses in the spectrum may teach us a good deal about the nebulæ which have so-called "continuous" spectra. After such a definite statement by Dr. Huggins as to the existence of irregularities, it is highly desirable that further observations and measurements should be made. Carbon comparisons (spirit-lamp flame) are suggested.

(3) A star of Group II., with bands 2, 3, 5, 7, 8 so narrow that Dunér describes them as "little more than lines." Narrow bands are common to both the early and late species of the

group, but in the former case the bright carbon flutings are strongly developed, whilst in the latter they are barely visible. Another characteristic of the later species is the addition of absorption-lines to the narrow bands. The observations of Mr. W. J. Lockyer and myself show that δ Piscium represents a late stage of the group, there being little or no carbon radiation.

(4, 5) Stars of the solar type. The usual differential observations are required.

(6) A star of Group IV. Observations of the relative thicknesses of the hydrogen and additional lines should be made, and the characters and positions of the latter noted. It appears that in some of these stars the added lines are similar to those seen in α Cygni, whilst others are solar.

(7) In this star of Group VI. the blue zone is very pale, the carbon band λ 564 is very wide and dark, and band 4 is suspected (Dunér).

(8) There will be a maximum of this variable on October 31. The period is about 138 days, and the range from 7·5–8·5 to 2·5–13·0. According to Dunér, the spectrum is one of Group I., but excessively weak. More details may possibly be obtained if the spectrum be observed at maximum. A. FOWLER.

SPECTROSCOPIC OBSERVATIONS (SAWERTHAL'S COMET 1881 I., AND β LYRÆ).—Dr. Nicolaus von Konkoly, the Director of the Astro-physical Observatory in O'Gyalla (Hungary) has issued the volumes containing his observations made during 1888-89. He notes, with respect to Sawerthal's comet (1881 I.):—

"I have observed the spectrum with a Merz universal spectroscope having one prism in position. This gave a dispersion of 8° (H to D), which was more than sufficient for my purpose. I was obliged to use this instrument, because the deviation it gave suited the focussing arrangement of the Kartaler refractor. The telescope of the spectroscope magnified seven times.

"The continuous spectrum was not very bright, and faded away slowly at each end. I thought that I could distinguish the D line (dark). It was so weak, however, that I could not fix its position with the micrometer. The continuous spectrum extended from 673 μ to 435 μ. Besides this I was able to recognize five hydrocarbon bands which I have located five times. From these measurements I have deduced the following mean values: I. 561·46 μ, II. 546·25 μ, III. 515·88 μ, IV. 513·26 μ, V. 472·56 μ.

"The lines were not sharply defined on either side, and were much widened near the continuous spectrum. The measurements given above are of the middle of the maximum light-intensity of the bands, which could be easily distinguished."

β Lyræ was spectroscopically observed on January 1, 1889, and it is recorded:—"The C line was bright and could be easily seen, and a dark band was visible at a slight distance from it. D_3 was distinguished in a similar manner. Near it, in the green, some fine lines could be perceived. F was suspected, but it was almost invisible."

Dr. Konkoly gives an extended account of his observations of Jupiter from 1885 to 1889, and accompanies it with a series of fourteen drawings of the planet. Several drawings of Sawerthal's comet are also given.

SPECTROSCOPY AT PARIS OBSERVATORY.—M. Deslandres has charge of the spectroscopic section just created at Paris Observatory, and in the current number of *Comptes rendus* (October 20) he gives an account of the instruments to be used with the great equatorial (1·20 metres aperture). Those who have tried to obtain photographs of star spectra by means of a slit spectroscope on a large telescope, know how difficult it is to adjust a star on the slit, and, when there, to keep it in position for a sufficiently long time. To enable this to be done during a long exposure, M. Deslandres has arranged a total reflecting prism near the dark slide, so that the red end of the spectrum may be seen whilst the blue end is being photographed. In this way he has obtained many photographs of stellar spectra in juxtaposition with comparison spectra. To adjust the instrument for observing, the spectrum of a star, a small mirror, having a hole in the centre about the same diameter as the length of the slit, has been fixed in front of the slit at an inclination of 45°. The image of a star is thus reflected to the side of the instrument, and after another reflection reaches a small telescope fixed at the spectroscope. This telescope, therefore, gives the image of a star in the plane of the slit, and constitutes a veritable finder for use with the spectroscope.

ON THE LATER PHYSIOGRAPHICAL GEOLOGY OF THE ROCKY MOUNTAIN REGION IN CANADA, WITH SPECIAL REFERENCE TO CHANGES IN ELEVATION AND TO THE HISTORY OF THE GLACIAL PERIOD.[1]

DR. G. M. DAWSON has been engaged continuously for seventeen years in geological exploration of the Western Territories of Canada, including the country from Lake Superior to the Pacific; and in the paper above named he summarizes the history of the successive deposits and earth-movements which have built up the mountain ranges of the West, and the relations of these to the geology of the great plains to the eastward. He devotes special attention to the Glacial age, and concludes that the drift phenomena of the plains belong to a period of submergence, and that in the extreme period of glaciation there were great glaciers on the Cordillera on the west, and the Laurentian axis on the east, with a vast internal sea between. He is thus entirely opposed, as far as North America is concerned, to the idea of a Polar ice-cap or a great continental glacier flowing down the interior plateau of the continent, and he resolves the phenomena of the ice age into the operation of huge mountain glaciers and floating ice.

The leading points of the memoir may be summarized, with the aid of a few extracts, in such a manner as to convey a general view of the history of the great Cordilleran belt, which stretches along the west coast of America from Behring Straits to Cape Horn, and more especially to indicate that of its more northern portion.

The general structure of the country may be defined as follows:—

"At the present day, the western border region of the continent is formed by a series of more or less nearly parallel mountain systems, with an average breadth in British Columbia of about 400 miles. The trend of these systems is north-west and south-east, or similar to that of the corresponding portion of the Pacific shore-line, the position of which, in fact, depends upon that of these orographic features. This generally mountainous zone of country is often referred to as the Rocky Mountain region, but is more appropriately named the Cordillera belt, the Rocky Mountains proper constituting only its north-eastern marginal range. In traversing it from east to west, in the southern part of the province of British Columbia, four distinct mountain-systems are crossed: (1) the Rocky Mountains proper, (2) mountains which may be classed together as the Gold Ranges, (3) the Coast Ranges, (4) an irregular mountain-system which in its unsubmerged parts constitutes Vancouver Island and the Queen Charlotte Islands, and which may be designated the Vancouver system. Between the second and third of these mountain-systems is a region without important mountain ranges, which is referred to as the Interior Plateau of British Columbia.

"To simplify our conception of the main features of this part of the Cordillera for our present purpose, we may, however, regard it broadly as being outlined on the north-east and south-west sides by the Rocky Mountains proper and by the Coast Mountains, as dominant ranges. This view is justified by the remarkable constancy of these two ranges and their relative importance. The intervening region may then be described as comprising the Interior Plateau together with the various ranges which have been grouped together under the name of the Gold Ranges, as well as other detached mountains and irregular mountainous tracts."

The geological history of British Columbia begins, like that of many other parts of the world, with that primitive crumpling of the earth's crust which produced the Laurentian gneisses. These exist principally in the Gold Ranges, and are in this region neither greatly extended nor of great elevation. In the Palæozoic age there were sea-bottoms receiving sediment, but apparently little mountain-making.

"Omitting, then, from consideration the imperfectly-known progress of events in the earlier stages of the geological history of the region, we may endeavour to picture to ourselves its condition in the Triassic or first stage in the Mesozoic division of geological time. The central region of the continent was at this time occupied by a very extensive, though shallow, mediterranean sea, which was either entirely cut off from the ocean

[1] By Dr. G. M. Dawson, F.G.S., Assistant Director of the Geological Survey of Canada. Transactions of the Royal Society of Canada, 1890. 73 pages quarto, with 4 maps.

or had only occasional and brief connection with it, and in which red beds with occasional layers of gypsum and salt were being deposited.[1] Rocks which represent a portion of the bed of this inland sea enter into the composition of the Rocky Mountain Range near the forty-ninth parallel, but are not known to occur to the north of that parallel for a distance of more than thirty or forty miles. To the west, they are not found in the Selkirk or Purcell Mountains. We appear, in fact, to discover in this vicinity the northern end of the inland Triassic sea. To the west of the Gold Ranges (under which term it will be remembered that the Selkirk, Purcell, and other mountains are grouped), deposits, also referable to the Triassic period, and more particularly to its upper part, are again found. These occur both on the mainland of what is now British Columbia and on Vancouver Island and the Queen Charlotte Islands. They contain truly marine fossils, and consist largely of materials of volcanic origin, which give evidence of contemporaneous volcanic activity on a great scale. To the north, in the Peace River country, and to the east of the present position of the Rocky Mountains, rocks holding the same marine forms are found, and they have quite recently again been discovered by Mr. McConnell in a similar position, still further north, on the Liard River.

"It would thus appear that in Triassic times the eastern border of the Pacific washed the western slopes of the Gold Ranges, and that where this mountain-system became interrupted, in its northern part, the sea was continued across its line, and covered a large tract of country to the east of the present position of the Cordillera belt.

"Precisely how far to the east the shore of this northern expansion of the Pacific was situated has not yet been determined. The region between it and the northern end of the inland sea previously referred to must have been a land area, which separated the open ocean of the north from the Mediterranean on the south. The Rocky Mountains proper had not yet been formed, nor is there any evidence of mountain ranges in the region of the Coast and Vancouver systems of to-day, though the volcanic action there in progress may have produced insular volcanic peaks. The deposits of the inland Triassic sea, including as they do beds of salt and gypsum, appear to prove the existence of a very dry climate in the area occupied by it; and as the land barrier separating it from the moisture-bearing westerly winds of the Pacific cannot have been wide, it must have been high. It is thus probable that the mountains of the Gold system formed at this time a lofty sierra, which was continued to the south of the forty-ninth parallel by the Cabinet, Cour D'Alaine, Bitter Root, and other mountains at least as far as the Wahsatch Range in Utah.

"The Triassic period was closed by one of those epochs of folding and dislocation of strata which are found to be recurrent in geological time, and which are generally attributed to the secular contraction of the earth's crust. The evidence of this time of change has been examined in greatest detail in the vicinity of the present coast-line, where it resulted apparently in outlining the Vancouver and Coast Ranges, and was accompanied by the production or extravasation of great masses of granitic rocks.[2] It is highly probable that some corrugation along the line of the Rocky Mountains occurred at the same period, as, in the next succeeding Earlier Cretaceous strata, without further evidence of disturbance, conglomerates are found to be composed of fragments of many varieties of the older rocks, which could scarcely otherwise have been rendered subject to denudation. Though much remains to be discovered respecting this post-Triassic epoch of disturbance, it was evidently an important one, and its results were wide-spread in the Cordillera region. It is quite possible that it was accompanied by, or resulted in producing, a general elevation of this entire region above the sea-level, as no rocks distinctly referable to the Jurassic or next succeeding period have yet been distinctly recognized either in British Columbia or in its bordering regions.[3] It must be borne in mind, however, that a portion of the red beds of the inland sea, described as Triassic, may extend upward into the Jurassic period, and that the marine Triassic fossils of the western and northern sea are referable to the later stages of the Triassic, or 'Alpine Trias' of the Cordillera region, comparable with the St. Cassian and Hallstadt beds of the Alps in Europe; while the beds of the Cretaceous next found are, according to European analogies, near the base of that formation."

"The next distinct record of the physical conditions of the region under discussion is afforded by the Earlier Cretaceous rocks. These, on the evidence of contained molluscan fossils, are regarded as about equivalent to the Gault of England, though the associated remains of plants are such as to admit their assignment to a somewhat older date. At this time, the immediately post-Triassic elevation had been followed by a subsidence of the land, resulting in the re-occupation by the open sea of the great area which had been similarly characterized in the Triassic. As in Triassic times, we find that this Earlier Cretaceous extension of the Pacific, to the north of the fifty-fourth parallel, spread eastward in a more or less connected manner completely across the present position of the Cordillera belt, while the Gold Ranges, and probably also other insular areas, continued to exist as dry land. In this case, as in that of the Triassic, it has not yet been found possible to outline exactly the eastern limit of the sea, in consequence of the want of sections cutting down to the base of the Cretaceous in the area of the Great Plains. There are, however, reasons for believing that it did not extend far beyond the line of the present foot-hills of the Rocky Mountains.

"In one important particular, the conditions in this Earlier Cretaceous period differed from those of the Triassic. There was at this time no isolated inland sea, and waters in connection with the main ocean stretched southward to the east of the Gold Ranges as far as the forty-ninth parallel and beyond it to a further distance which is as yet undetermined. This extension of the open sea thus actually overlapped, to a considerable extent, the area formerly occupied by the Triassic mediterranean."

This was followed, however, in Middle and Later Cretaceous times, by a great depression in which the marine beds of the Neobrava and Pierre Groups were deposited. This submergence was succeeded by some measure of elevation or folding, leading to the existence of vast swampy and lacustrine flats, in which the lacustrine and peat deposits of the Laramie formation of the great plains were formed. These deposits may be regarded as closing the Cretaceous era, or as transitional between it and the Eocene.

"This state of affairs was brought to a close by another of the recurrent epochs of folding and dislocation of the earth's crust, which was one of the greatest of those of which we find the results in the region under discussion, as well as the last of an important character to which this region was subjected. Under the influence of enormous pressure acting from the Pacific side, the nearly horizontal strata, which bordered the Gold Ranges on the north-east, were folded together and thrown up into a dominant ridge of Alps, which finally outlined the Cordilleran belt on this side. A similar folding and upthrust affected also the western marginal mountains which have been referred to as the Vancouver Range, but the action was there probably less violent and certainly affected a narrower zone. A portion of the crumpling to which the rocks of the Coast Ranges have been subjected was doubtless also produced at or about the same time, and certain granitic extrusions which cut the earlier Cretaceous rocks on its eastern flanks, as well as much of the flexure of these Cretaceous rocks, are also attributed to this period of disturbance.

"There is really no means of ascertaining what effect this disturbance produced in the region of the Gold Ranges, but it is more than probable that the whole width of the Cordillera then suffered changes and deformation of such a character that little if any trace of its surface contour of an older date can be found to-day.[1] It does not, however, necessarily follow that the

[3] Certain rocks, from which fossils supposed at the time to be Jurassic were described, have since been found to belong to the Earlier Cretaceous. Cf. "Report of Progress, Geological Survey of Canada," 1876–77, p. 150; "Mesozoic Fossils," vol. i. p. 258.

[1] In respect to this great epoch of orographic movement, as evidenced particularly in the more southern part of the Cordillera, which has now been somewhat closely studied, Mr. S. F. Emmons may be quoted as follows:—"It is unquestionably one of the most important events in the orographic history of the entire Cordilleran system. With the exception of the great unconformity between the Archæan and all overlying sediments, which is a phenomenon *sui generis* and altogether exceptional, no movement has left such definite evidence as that which follows the deposition of the coal-bearing rocks to which the name Laramie has by universal consent been applied."—*Bulletin Geol. Soc. Amer.*, vol. i. p. 285.

general altitude of the Cordillera belt was at this time materially changed. The greater part of the accumulated pressure appears to have been relieved by folding along the lines of its two bordering ranges, and it seems to be not improbable, as a general proposition, that changes in elevation affecting wide areas are due to other causes than those producing mountain ranges.[1] We are warranted in assuming, however, that a certain movement in elevation was coincident, or nearly so, with that of the great disturbances above outlined, as no strata representative of the Eocene period proper have yet been found anywhere in the western part of Canada. The entire area of the Great Plains was thus sufficiently elevated to become dry land, as occurred at the same time in the Western States to the south of the international boundary."

The Eocene period thus witnessed the formation of the great interior table-land, which accordingly has present no aqueous formations of this age. In Miocene times, however, there were large interior lakes, with deposits rich in remains of plants and insects, and on the plains fluviatile gravels with mammalian bones.

The Pliocene period inaugurated another great continental elevation, which continued for a long period, and in which the fiords and cañons of the Cordillera were cut down by fluviatile action to the sea-level of the period. Many local illustrations are given in this memoir of the curious results in regard to denudation which this period of rest and elevation produced.

This leads to the glacial history of the region, the key to which is believed to be found in the unequal elevation whereby, while the great plains to the east remained under water, the Cordilleran Ranges became covered with a great glacier discharging north toward the Yukon Valley and the Arctic Sea, and south to Puget Sound, while glacial streams ran westward to the Pacific. At this time the Rocky Mountains produced but few and small glaciers on their eastern sides; but across the wide sea which covered the plains the Laurentian Mountains supported another *névé* discharging ice in all directions.

This was followed by what is usually called the inter-glacial period, when, as is believed, the plains were slightly elevated and the mountains depressed; and this was succeeded by the second glacial period, in which the mountain glaciers were comparatively small, and the depression of the plains was so great that water-borne boulders were deposited at elevations of 5000 feet or more on the foot-hills of the Rocky Mountains. It is to be noted here that the present eastward slope of the western plains had not yet been impressed on them. The series of events thus indicated is illustrated by the following table, which, however, the author regards as somewhat provisional:—

SCHEME OF CORRELATION OF THE PHENOMENA OF THE GLACIAL PERIOD IN THE CORDILLERAN REGION AND THE REGION OF THE GREAT PLAINS.

Cordilleran Region.	*Region of the Great Plains.*
Cordilleran zone at a high elevation. Period of most severe glaciation and maximum development of the great Cordilleran glacier.	Correlative subsidence and submergence of the Great Plains, with possible contemporaneous increased elevation of the Laurentian axis and maximum development of ice upon it. Deposition of the lower boulder-clay of the plains.
Gradual subsidence of the Cordilleran region and decay of the great glacier, with deposition of the boulder-clay of the Interior Plateau and the Yukon Basin, of the Lower boulder-clay of the littoral, and also at a later stage (and with greater submergence) of the inter-glacial silts of the same region.	Correlative elevation of the western part of the Great Plains, which was probably more or less irregular, and led to the production of extensive lakes in which inter-glacial deposits, including peat, were formed.
Re-elevation of the Cordilleran region to a level probably as high as or somewhat higher than the present. Maximum of second period of glaciation.	Correlative subsidence of the plains, which (at least in the western part of the region) exceeded the first subsidence, and extended submergence to the base of the Rocky Mountains near the forty-ninth parallel. Formation of second boulder-clay, and (at a later stage) dispersion of large erratics.
Partial subsidence of the Cordillera region to a level about 2500 feet lower than the present. Long stage of stability. Glaciers of the second period considerably reduced. Upper boulder-clay of the coast probably formed at this time, though perhaps in part during the last.	Correlative elevation of the plains, or at least of their western portion, resulting in a condition of equilibrium as between the plains and the Cordillera, their *relative* levels becoming nearly as at present. Probable formation of the Missouri Côteau along a shore-line during this period of rest.
Renewed elevation of the Cordillera region with one well-marked pause, during which the littoral stood about 200 feet lower than at present. Glaciers much reduced and diminishing, in consequence of general amelioration of climate toward the close of the Glacial period.	Simultaneous elevation of the Great Plains to about their present level, with final exclusion of waters in connection with the sea. Lake Agassiz formed and eventually drained toward the close of this period. This simultaneous movement in elevation of both great areas may probably be connected with the more general northern elevation of land at the close of the Glacial period.

Among the evidences given of the partial submergences and differential elevations stated in this table, reference is made to the "White Silt formation" so extensively distributed in many parts of British Columbia, and indicating water action up to levels of about 2700 feet, to the high-level terraces; the peculiar distribution of boulders from the Laurentian highlands on the eastern slopes of the Rocky Mountains; the absence of glacial abrasion on the plains; the chemical character of the boulder-clay, leading to the inference that it was formed under water; the wide distribution and characters of the inter-glacial beds, the character and position of the Missouri Côteau, and a variety of other local facts. The objection that marine shells are not found in the Pleistocene strata is treated thus:—

"From what has already been said with respect to the Cordillera region, and more particularly in connection with the meaning which the White Silt formation appears to have in that region, it seems probable that the water by which the northern part of the Great Plains is supposed to have been flooded was in connection with that of the sea.[1] In discussing the results of my earlier investigations of the superficial deposits of this part of the plains, in reference to a theory of their submergence, I have stated that after a certain stage the waters entering from the north and south must have formed an open strait between the Arctic Ocean and the ocean to the south.[2] This was written, however, under an assumed limitation implying an equal subsidence of the continent; and at the time no satisfactory information was available respecting the position of the margin of the glacial deposits in the corresponding western part of the United States, such as has since been supplied by the work of Chamberlin, Salisbury, Todd, Wright, McGee, Upham, and others. The result of these new facts appears to show that, instead of opening broadly southward as well as to the north, any body of water covering the northern part of the Great Plains could have had only a tortuous and comparatively narrow communication with the sea to the eastward, round the front of the great confluent Laurentide glacier, and that even this communication was probably formed only at the time during which the plains stood at the lowest level indicated by the spread of the drift deposits. If such conditions may be assumed as probably

[1] Cf. Le Conte, *American Journal of Science*, III. vol. xxxii. p. 178.

[1] It must still, however, be admitted as possible, that a great lake was in some manner produced, in the region of the plains, with a height somewhat exceeding that of the sea.

[2] "Geology and Resources of the Forty-ninth Parallel," p. 255.

representing the facts at the time, they go far toward explaining one of the greatest difficulties against the acceptance of the hypothesis that the waters by which the plains were flooded were in communication with those of the sea. The difficulty alluded to is the complete absence, so far as yet ascertained, of the remains of marine organisms from the glacial deposits. While prolonged weathering and the action of sub-aërial waters might result in the removal of calcareous organic remains from certain parts of these deposits, the condition of much of the boulder-clay, together with the occasional actual occurrences in it of fragments of Cretaceous or Laramie shells, is such as to show that any contemporaneous mollusks might have been preserved. If, however, the body of water in question, though communicating with the sea to the northward, was almost throughout closed to the south and in receipt of large quantities of fluvial water, it may well have been in great part brackish, if not almost entirely fresh. Adding to this the conception of its frigid temperature due to the great abundance of ice with which it must have been laden, and the vast amount of fine sediment which must have been carried into it by sub-glacier streams, it will be apparent that the conditions were singularly inimical to the existence of life of any kind, whether that characteristic of salt or fresh water. Somewhat similar conditions, though on a much smaller scale and without the adjunct of glacial waters or glaciers, occur in the southern extremity of Hudson Bay, where, as Mr. A. P. Low informs me, marine life is almost entirely absent, the water being nearly fresh and clouded with mud derived from the large entering rivers and from the action of the waves upon the shallow earthy shores."

Finally the climatal conditions deducible from the geological facts coincide with these facts in enforcing the probability that the great ice age of North America depended mainly on the existence of high mountains, surrounded by submerged areas, traversed by ice-laden currents, and that we are to imagine, not a continent covered with ice, but a submerged continent, with snow-clad mountains rising at its margins, and forming the gathering grounds of great local glaciers—the *Cordilleran*, the *Laurentide*, and probably the *Appalachian* glaciers. These were the favouring conditions, but the author does not venture to deny the co-operation of other and cosmical causes. He concludes as follows:—

"When the study of the superficial deposits of different parts of Europe and America was for the first time seriously begun, it was endeavoured to explain the phenomena entirely by diluvial action, and when the evidence of ice-action became insuperable, icebergs and floating ice only were at first admitted as factors. Since that time the pendulum of opinion appears to have swung to the opposite extreme, and the energies of the majority of investigators have been extended in endeavouring to account for the varied facts of what has become definitely known as the Glacial period, almost exclusively by the action of great confluent glaciers. From this extreme point, the pendulum may now be supposed to have returned so far, as to leave the hypothetical North Polar ice-cap almost without an advocate, but at what position it may eventually come to rest time alone can decide. I am aware that some of those who have accepted what I may perhaps be pardoned for characterizing as extreme views as to glacier action, have more or less completely, and to their own satisfaction at least, solved all difficulties opposed to the action of land ice, such as those presented by the facts met with over the Great Plains, by the application to these of their single universal menstruum. For myself I need only say that I have endeavoured to approach the subject of the glaciation of the north-western part of the continent, here reviewed, untrammelled by *a priori* theories, and with some personal familiarity in the field with nearly all parts of the region dealt with."

The above is only a hurried and imperfect summary. The paper itself, as containing the matured conclusions of long and thorough investigation by an able and earnest explorer, should be carefully read by all interested in the structure of the Great Cordilleran backbone of the American continent.

THE SCIENTIFIC INVESTIGATIONS OF THE FISHERY BOARD FOR SCOTLAND.[1]

THE results of the scientific investigations for 1889 are given in full detail with numerous tables and two charts. It was found that, during the year, no increase but rather a decrease, mainly in the migratory round fishes, occurred in the closed waters, and likewise in the open waters adjacent, the results of 1887 having been proved exceptional. The results of concurrent investigations carried on on board the *Garland* into the food of fishes, their spawning, and the distribution of the young, show that great and important differences—which must be taken into consideration both from a scientific and legislative point of view—prevail among the various food-fishes (Section A).

Dr. Wemyss Fulton, in his paper on the distribution of immature sea-fish and their capture by various modes of fishing, gives the results of the investigations into this important subject. The fundamental question as to what an immature fish is, has been determined for the first time by the examination and measurement of 13,000 fishes. The maximum size (as given in detailed tables) varies very much according to the species; any law regulating the legal sale of fish on the principle of size is therefore not based on scientific data. The distribution differs in the same way, but territorial waters serve as nurseries for the young fish. Tables given show the distribution of immature fishes at distances from the shore up to 22 miles and in various depths of water. Details are also given as to the proportion of immature food-fishes captured by the various modes of fishing. Dealing practically with the wasteful destruction of immature food-fishes, Dr. Fulton points out the difficulty of deciding among the different species, and shows how difficult it will be to save immature fish from capture and destruction by the beam-trawl, as that engine is now employed. The recommendations briefly are: that an inquiry should be made as to the retention of vitality by the various kinds of immature fish brought up in the trawl in order to ascertain the chances of survival if replaced in the sea; the protection of nurseries whose areas are capable of definition; the preservation of flat-fish under a certain size; and the establishment of hatcheries for sea-fish. A simple method is explained by which fishermen and trawlers might add to the fish-supply by fertilizing the ova of ripe fish when captured.

Regarding this Report, it should be noted that the importance of this question is not a thing which has dawned upon the Scottish Fishery Board since the conduct of scientific investigations was placed under new management (that of Dr. Fulton). In this paper, as in many others—indeed, everywhere in this year's Report—the willingness to ignore all that was done during the years that Prof. Ewart was convener of the Scientific Committee is very evident. In the Report of 1887 it is stated that "We have organized a series of extensive and systematic inquiries into the conditions of the reproductive organs of various kinds of fishes throughout the entire year, with particulars as to their size, &c., *which will help to clear up the hitherto obscure problems as to the minimum size of sexually mature individuals, &c.*" We have certain information that the original discoveries which led to this Report on immature fish were made by one who has done more than his share to redeem the work of the Fishery Board. And it is only fair that the credit which is Mr. T. Scott's due, and which is denied him there should be acknowledged here.

Dr. Fullarton furnishes a Report, with chart, on the cockle-beds of Barra (in the Hebrides), which furnishes the chief cockle-fishing in Scotland. It is desirable—and the wish of the fishermen themselves—that means should be taken to prevent the taking of undersized cockles, and to insure the working of the beds in rotation.

Dr. Fullarton also gives a paper on oyster-culture fauna in France and Holland. It is most desirable that scientific and practical measures should be taken to revive the Scotch oyster-fishing, which has gradually declined, and these should be planned on known and tried lines. The same must be said of the cultivation of mussels, and this should be urged even more strongly, as their scarcity or abundance are of the utmost importance to the line-fishermen. Lobsters also call for practical legislation and artificial cultivation. The Fishery Board are constructing a lobster inclosure at Brodwick, Arran, and hope that means will be provided for their carrying on operations at the recently established hatchery at Dunbar.

Section B contains the biological investigations. The food of fishes was dealt with in an elaborate Report by Mr. Ramsay Smith, based upon the examination of many thousand food-fishes which prove to live chiefly upon Crustacea, Annelids, Echinoderms, Mollusks, and upon one another. There are great differences, however, as to the proportion of the organisms selected as food by different fishes, and the proportions of the

[1] "Eighth Annual Report of the Fishery Board for Scotland." Part III. Scientific Investigations.

dietary vary to some extent at different places and at different seasons. These observations will ultimately demonstrate what organisms are valuable as fish-foods and what are not; the proportion in which the various vertebrates compose the dietary of fishes; and the possibility of introducing a valuable food-fish, such as the English sole, in places where it is absent or scarce. They will also show in what way the organisms forming the food of fishes may be protected and improved.

In a Report on the spawning and spawning-places of food-fishes, Dr. Fulton describes the results of the observations made during the year, many thousands of fishes having been examined on board the *Garland* all along the coast, and the duration of their spawning period in most instances determined. The duration of the spawning period varies much in different fish, and in some cases fully-grown adults appear not to spawn every year. The majority of the food-fishes congregate at the spawning time in immense shoals on the east coast at grounds lying from about eight to above twenty miles from shore in what may be termed the extra-territorial spawning zone. The young fishes are not, as a rule, found at the place of spawning, the floating pelagic eggs being carried by the currents chiefly shorewards. Dr. Fulton gives reasons for the belief that the selection of a particular offshore ground for spawning depends upon the set of the surface currents at the spawning season, these carrying the floating eggs during their development to the zones where food for the young fishes is abundant and shelter most readily secured.

Prof W. C. McIntosh has made an elaborate study of the pelagic fauna of St. Andrews Bay, of which the second part, dealing with the distribution of the invertebrate organisms which form the food of many larval and other fishes, is now given.

Prof. McIntosh has also, in another paper, described the ova of the food-fishes and the larval and post-larval stages obtained in the *Garland's* tow-nets at various parts of the coast. These include the ova or larvæ of plaice, lemon-sole, flounders, dabs, cod, haddocks, ling, whiting, &c., and they constitute an indispensable part of the general study of the reproduction of the food-fishes.

Mr. Thomas Scott, in his valuable additions to the fauna of the Firth of Forth, gives a list of 80 species of organisms, not previously recognized as belonging to that locality. Some of these are for the first time recorded from the east of Scotland; some are new to Britain, and a few new to science. This paper is illustrated by two plates.

Mr. Scott, in his Report on the invertebrate fauna of inland waters, gives the result of the first investigations into the invertebrate organisms present in Scottish lochs and inland waters ever carried on in this country.

Dr. Fullarton's paper on the development of the clam is one which would hardly have found acceptance in any scientific journal. Had text and plates been submitted to the judgment of a skilled investigator, there would have been little or nothing of either for publication, as both display gross inaccuracy. There are many very remarkable statements in this paper, and the author naively describes as normal, phenomena whose pathological nature the merest tyro ought to be able to recognize.

Dr. John Beard, in his paper (illustrated by three plates) on the development of the common skate, gives the result of the study of this subject, on which very little has been written, though the skate is one of the most common elasmobranch fishes of our seas. The development of the embryo as it lies within its "purse" at the bottom of the seas occupies probably nine or ten months, being more rapid in summer than in winter. The eggs may be deposited throughout the year, but chiefly in March and April. Dr. Beard furnishes minute descriptions of the egg-cases or "purses" of the various species of skates and rays, and of the various stages in the development of the embryo. He discusses the function of the temporary external gills, so characteristic in advanced stages of development; and, in opposition to other authorities, he gives good reason for the belief that they are purely respiratory in function, and are adapted to the special conditions under which the developing embryo is placed.

Dr. Fulton, in his paper on the proportional numbers and sizes of the sexes among sea-fishes, gives the results of his inquiries, based upon the examination of 12,666 fishes. Females are, as a rule, more numerous than males; the female is also as a rule larger, but the male is the larger among the cod, haddock, and a few other fishes.

Among the "Notes and Memoranda" will be found Mr. Scott's hybridism among fish, the account of ingenious and interesting experiments made on board the *Garland* on the artificial fertilizing of the ova of certain species of sea-fishes with the milt of other species sometimes widely separated zoologically. Dr. Fulton sends interesting notes on the reproduction and migrations of the common eel, and on the presence of anchovies in Scotch waters. Regarding the former paper, it should be remembered that a German zoologist recently obtained a conger-eel at Zanzibar with eggs ten times the size of those here described. There is nothing really remarkable in the reproductive organs of the eel obtained at Howietoun, eels with eggs as large being very often caught. It has usually been estimated that the eel produces five millions of ova. The number is here increased to upwards of ten millions, and the method by which this was counted is not given. There is a lamentable looseness in quoting literature, even that of British zoology. We are told that *Myxine* is a protandric hermaphrodite, and that this was discovered by Nansen. As a matter of fact, the discovery was made by a Scotch naturalist (Cunningham), and within a short distance of Edinburgh. If Nansen's paper had been read as well as quoted, this misstatement would not have been made.

Section C contains notes on contemporary work relating to fisheries in this and other countries. We note that no mention is made, however, of the very important "Plankton" expedition of Germany of last year, which is the more to be wondered at as interesting accounts of the expedition have been published in Germany.

It is much to be regretted that the Fishery Board Bill of last year did not become law. The conduct of scientific investigations might then have been placed in different hands, with the result, among other things, that properly-organized scientific work would have been carried on by a thoroughly competent scientific staff, and the Government grant of £2000 a year usefully and judiciously expended, instead of being, as at present, frittered away because the dominant clique of the Fishery Board do not know what to do with it. The Scientific Department of the Fishery Board needs reorganization quite as much as the Fishery Board itself. Under the control and direction of the leading Scottish biologists, some adequate return ought to be made for the nation's money. To do this, however, the work must be properly planned and directed, and moreover the working of the different investigations given only to men who really understand their subject. Government has been asked, and is asked in the present Report, to furnish increased funds. We hope and believe that the authorities will be wise enough to stay their hand till they can reorganize everything connected with the Fishery Board.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Mr. Love, St. John's, and Mr. Coates, Queens', have been appointed Moderators, and Mr. Wallis, Corpus, and Mr. Burnside, Pembroke, Examiners for the next Mathematical Tripos, Part I.

Mr. L. Fletcher, Keeper of Minerals at the British Museum, and Mr. H. P. Gurney, of Clare College, are nominated Examiners in Mineralogy for the Natural Sciences Tripos.

Mr. H. M. Stanley was, on October 23, admitted to the honorary degree of LL.D.

The following communications were made to the Cambridge Philosophical Society at the annual general meeting on October 27:—The President, the origin and early years of the Society; Mr. C. Chree, on the vibrations of some simple systems; Dr. A. Gamgee, on the principle on which Fahrenheit constructed his thermometrical scale; Mr. H. J. Sharpe, on liquid jets.

The Harkness Scholarship for Women, tenable at either Girton College or Newnham College, Cambridge, is to be awarded triennially to the best candidate in an examination in geology and palæontology, provided that sufficient proficiency is shown. The candidates must be resident members of Girton or Newnham College, in their first or second term. The Scholarship will be of the value of about £35 a year for three years. The next award will be made in 1891. The examination will be held at Cambridge in the Michaelmas Term, and the award will be made on or before November 15, 1891. The intended range of examination is indicated by the following schedule:—General physical geography; such geological phenomena as are matters of common observation; the principal agencies which change or modify the earth's surface and the life on it; outlines

of the stratigraphy of the United Kingdom; outlines of the classification of organized beings, existing and extinct; the commoner rocks and rock-forming minerals, and the commonest and most characteristic British fossils. Candidates must send in their names, on or before October 12, 1891, to Miss A. Johnson, Llandaff House, Cambridge, from whom further information may be obtained.

SCIENTIFIC SERIALS.

American Journal of Science, October 1890.—A description of the "Bernardston Series" of metamorphic Upper Devonian rocks, by Prof. Ben. K. Emerson. With respect to this paper, Prof. J. D. Dana remarks:—"Prof. Emerson has given the region a thorough investigation, in which he has removed the doubts as to the relations of the beds, made out, as far as possible, the system of faults and flexures, studied the rocks as to their kinds and transitions, and determined the age of the series to be Upper Devonian. The paper will be accepted in America, and should be elsewhere, as putting the facts beyond doubt that gneiss, diorite, granite, and the other crystalline rocks described are not always of Archæan or pre-Cambrian make; that granite and diorite are not always of igneous origin; and these conclusions are made sure on the well-established criterion of age, that is, fossils—Crinoids, Corals, Brachiopods."—On the circular polarization of certain tartrate solutions, by J. H. Long. The author describes certain peculiarities of solutions of potassium antimony tartrate, when mixed with potassium or sodium carbonate, acetate, or phosphate in amounts insufficient to produce immediate precipitation. A decrease of specific rotation took place in the case of each of the mixtures. It is probable, therefore, that a temporarily stable antimony salt is formed with a corresponding amount of alkali tartrate. The observed rotation is due to this in conjunction with that of the potassium antimony tartrate which remained unchanged.—A rapid method for the detection of iodine, bromine, and chlorine, in presence of one another, by F. A. Gooch and F. T. Brooks.—Metacinnabarite from New Almaden, California, by W. H. Melville.—On the Keokuk Beds at Keokuk, Iowa, by C. H. Gordon.—Note on the vapour-tension of sulphuric acid, with the description of an accurate cathetometer microscope, by Dr. Chas. A. Perkins. The author finds that the vapour-tension is not greater than about 0·01 mm. at ordinary temperatures.—Experiments upon the constitution of the natural silicates, by F. W. Clarke and E. A. Schneider.—On five new American meteorites, by George F. Kunz. Descriptions and analyses are given of the group of meteorites recently discovered in Brenham Township, Kiowa County, Kansas; the Winnebago County, Iowa, meteorite; the meteoric stone from Ferguson, Haywood County, North Carolina; the meteoric iron from Bridgewater, Burke County, North Carolina; and the meteoric iron from Summit, Blount County, Alabama.—On the determination of the coefficient of cubical expansion of a solid from the observation of the temperature at which water, in a vessel made of thin solid, has the same apparent volume as it has at 0° C.; and on the coefficient of cubical expansion of a substance determined by means of a hydrometer made of this substance, by Alfred M. Mayer.

THE *American Meteorological Journal* for October contains articles:—On cyclical periodicity in meteorological phenomena, by E. D. Archibald, in which he advocates investigations as to the possible connection between weather and other physical agencies, on the following plan: (1) the collection and analysis of all previous investigations which bear traces of any value, and their distribution under the head of the particular element dealt with; (2) the arrangement of the periods in the matter of length; (3) the choice of the particular working hypothesis intended to be employed, and the working out of its supposed effects in different parts of the world; (4) the reduction and comparison of the data representing the various elements, and their comparison with the deductions from the hypothesis; (5) the investigation of the causes of apparent exceptions, and the exhibition of the final results, both in tabular and graphic form.—On accessory phenomena of cyclones, by H. Faye. The author draws attention to the theories of Redfield and Reid, and to the contradictory theories of Espy and Bache, from which he argues that only one conclusion could be drawn, viz. that there were two entirely different kinds of storms and tornadoes; and he refers to the advance made by the study of synoptic charts, both as regards the movements of cyclones and thunderstorms. The article contains an illustration of what he assumes to be a typical figure of a cyclone.—On temperatures in and near forests, by Prof. M. W. Harrington. The author shows that this subject admits of a much less satisfactory solution than that of soil temperatures discussed in an earlier paper. The observations used are from several sources over Central Europe, and refer in this part of the discussion to differences of temperature extremes. They show that the forest cuts off the mean daily maxima on the yearly average to the extent of 2° or 3°; the effect is most marked in summer and least in winter. The action of the forest on the minima of temperature is also a moderating one: the temperature does not on the average fall as low in forests as outside. With long-continued unchanging weather the peculiarities of forest climate tend to disappear.—On the Meteorological Section of the French Association for the Advancement of Science, held at Limoges in August last, by A. L. Rotch. The attendance of meteorologists was not large, but some important matters were discussed, among which may be mentioned the use of self-recording instruments on mountain stations, the subject being introduced by M. Teisserenc de Bort, and a paper on the recent seismic activity of Japan, by M. Y. Wada, of Tokio.

IN the *Journal of Botany* for October is a very interesting biographical sketch, accompanied by an excellent portrait, of the late Mr. John Ralfs, of Penzance, whose classical work, "The British Desmidieæ," one of the most valuable monographs ever published, was brought out as long ago as 1848. The value of this work may be judged from the fact that before its publication the number of species of Desmids recorded as British was four. An interesting note is given on the fertilization of the sugar-cane, by Dr. Fressanges, President of the Medical Society of Mauritius.

THE greater part of the number of the *Nuovo Giornale Botanico Italiano* for October is occupied by the completion of Signor L. Nicotra's interesting and important paper on the flora of Sicily. Going through the natural orders successively, he describes in general terms the representation of the order in the flora of the island, and points out the contrast between the flora of its north-eastern and that of its south-western portion, due to geological causes, the former having more of a European, the latter more of a North African character. Some particulars are added with regard to the flora of the small islands adjacent to Sicily. The remaining articles in the number are of special interest to Italian botanists.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 20.—M. Duchartre in the chair.—Study of the movement of a double cone which appears to rise, though it really descends, on an inclined plane, by M. H. Resal. A double cone placed on two guides inclined to the horizon, and nearer to one another at the lower than at the upper end, appears to ascend. The author has studied the mechanics of this movement.—Note on lightning-flashes which meet one another, by M. A. Trécul. On September 29, M. Trouvelot presented a paper on the identity in the structure of lightning and discharges from an induction machine. The author calls attention to the fact that he made similar observations ten years ago.—Observations of Brookes's comet (March 19, 1890), made with the great equatorial of Bordeaux Observatory, by MM. G. Rayet, L. Picart, and Courty. Seventy-one observations for position are given, extending from June 21 to October 12.—Remarks relative to a cause of variation of latitudes, by M. R. Radau. The movements of the sea, as well as certain meteorological phenomena (avalanches, &c.), may give rise to small deviations of the axis of our globe. It is shown that a mass of water 2000 cubic kilometres in size could produce an effect large enough to be observed.—On the established variations in the observations of the latitude of the same place, by M. A. Gaillot. Observations made at Berlin, Potsdam, and Prague, indicate that the latitude of a place is subject to a periodic variation, the maximum occurring in the summer, and the minimum in the winter, the amplitude of the oscillation about the mean value being ± 0"·25. M. Gaillot gives two hypotheses to account for this variation, and points out the means of testing each of them.

This attained a height of 418″, but was of a much more broken character than the preceding one.—On certain kinds of surfaces, by M. Lelieuvre.—Researches on the atomic weight of fluorine, by M. Henri Moissan. (See Notes, p. 649.)—Action of aromatic amines and of phenylhydrazine upon the β-ketonic nitriles, by M. L. Bouveault. The author establishes the generality of the reaction—

$$\mathrm{R{-}CO{-}C}\langle^{\mathrm{R'}}_{\mathrm{R''}}\rangle\mathrm{{-}CN + R'''NH_2 = H_2O + R{-}\underset{\underset{\mathrm{NR'''}}{\|}}{C}{-}C}\langle^{\mathrm{R'}}_{\mathrm{R''}}\rangle\mathrm{{-}CN.}$$

—On the mode of combination of sulphuric acid in plastered wines, and on a method of analysis permitting the distinction between the amount of the plastering and the acidification of the wine by sulphuric acid, by MM. L. Roos and E. Thomas. It is shown, by experimental means, that the sulphuric acid introduced by the plastering exists in the wine as K_2SO_4, and not as $KHSO_4$; hence, on precipitation of the H_2SO_4 by $BaCl_2$, the whole of the HCl will remain in combination, thus:—$K_2SO_4 + BaCl_2 = BaSO_4 + 2KCl$; and so the titrations of Cl by standard $AgNO_3$, taken (*a*) in filtrate from the $BaSO_4$ made up to a definite volume, and (*b*) in a fraction of the same filtrate evaporated to dryness, and then made up to the same fraction of the definite volume, should be exactly the same if no free H_2SO_4 be present; if free H_2SO_4 be present, a corresponding quantity of HCl will be lost to titration (*b*).—The saccharine matters in mushrooms, by M. Em. Bourquelot.—On the excretory apparatus of *Palinurus vulgaris*, *Gebia deltura*, and *Crangon vulgaris*, by M. Paul Marchal.—On the primitive conformation of the kidney of Pelecypodæ, by M. Paul Pelseneer.

STOCKHOLM.

Royal Academy of Sciences, October 8.—On the spectrum of absorption of bromium, by Prof. Hasselberg.—On the development of the Orthagoriscæ, by Prof. Smitt.—A report on entomological researches in the south of Sweden and Denmark, by Prof. Aurivillius.—Microscopical structures represented in coloured figures, which had been photographed by the firm Lumière, at Lyons, exhibited by Prof. Gyldén.—On the properties of a combination between nitrogen and hydrogen (HN_3) (discovered by Prof. Curtius, in Kiel), which in its free state, as well as in its combinations, has a most remarkable analogy with the hydrogen combinations of the haloids, and in consequence thereof has been named hydrazoic acid, reported upon by Prof. Nilson.—Studies of the crystal form of the arsenopyrite, by Dr. Weibutt.—Studies of naphthalene derivatives, by Dr. Paul Hellström.—Some observations on the anatomy of the subterranean elongations of the Gramineæ, by the same.—On the occurrence of *Dictyophyllum Nilssoni*, Brongn., in the coal-bearing strata of China, by Prof. Nathorst.—On Ribaucour's cyclic system, by Prof. Bäcklund.—Derivatives of ethyliden-disulphon-acids 1, and on 1, 4 fluor-naphthalin-sulphon-acid, by Herr Mauzelius.—Contributions to the knowledge of the moss flora of Canada, by Lector N. C. Kinberg.—Contributions to the theory of infinite determinants, by Herr H. von Koch.—On the conductibility of electricity through hot, saline vapours, by Dr. S. Arrhenius.

DIARY OF SOCIETIES.

LONDON.

SUNDAY, NOVEMBER 2.

SUNDAY LECTURE SOCIETY, at 4.—The Order of Nature—its Relation to Human Life and Happiness: A. Elley Finch.

THURSDAY, NOVEMBER 6.

LINNEAN SOCIETY, at 8.—A Contribution to the Study of the Relative Effects of different parts of the Solar Spectrum on the Assimilation of Plants: Rev. Prof. Henslow.

CHEMICAL SOCIETY, at 8.—The Magnetic Rotation of Saline Solutions: Dr. W. H. Perkin.—Note on Normal and Iso-propylparatoluidine: Hori and H. F. Mosley.—The Action of Ammonia and Methylamine on the Oxylepideus: Dr. F. Klingemann and Dr. W. F. Laycock.—Condensation of Acetone Phenanthraquinone: G. H. Wadsworth.

FRIDAY, NOVEMBER 7.

GEOLOGISTS' ASSOCIATION, at 8.—*Conversazione.*

SATURDAY, NOVEMBER 8.

ROYAL BOTANIC SOCIETY, at 3.45.
